# Nutritional and metabolic management of the diabetic patient with chronic kidney disease and chronic renal failure

*Mark E. Williams and Robert C. Stanton*

Harvard Medical School, Renal Unit, Joslin Diabetes Center, Boston, MA, United States

## Introduction

Diabetes mellitus (DM) has for sometime been the single largest contributor to the growing prevalence of chronic kidney disease (CKD) worldwide, rising over three decades in concert with the rising prevalence of diabetes itself. In the United States, 23% of all adults 60 years and older have DM [1]. It is estimated that the worldwide prevalence of DM will reach about 450 million people by the year 2030 [2]. Diabetic nephropathy affects 10%–20% or more of individuals with DM, the majority of whom have type 2 diabetes. While the risk of incident end-stage renal disease (ESRD) attributed to diabetes appears to have stabilized in the United States and elsewhere, the incidence of DM as well as its overall prevalence continue to increase. In a recent cross-sectional study of National Health and Nutrition Examination Survey (NHANES) data, about a quarter of CKD among all US adults was attributable to diabetes, after adjusting for demographic variables such as age and hypertension [3]. Diabetes is now the presumed cause of approximately half of incident ESRD cases [4], and its prevalence is expected to rise with the rising prevalence of ESRD in coming decades, although there may be an element of overreporting of the condition, which may not necessarily be the primary cause of the ESRD in a given patient [4]. Nonetheless, the dramatic rise in the global burden of disease and death attributed to diabetic kidney disease is among the highest for all chronic diseases [5]. The top three countries in terms of prevalence of diabetes are the United States, China, and India, with distributions of diabetic kidney disease shown in Fig. 42.1 [6].

The prevalence of the hallmark components of CKD [albuminuria and reduced glomerular filtration rate (GFR)] rises progressively with longer diabetes duration. Albuminuria and estimated GFR (eGFR) are predictors of ESRD and mortality in diabetic CKD. Because the combination of eGFR and albuminuria predicts outcomes better than either measure alone [7], risk assessment based on CKD staging level is increasingly utilized, including albuminuria to add prognostic information. It is clear that early and later phases of diabetic CKD may respond differently to similar therapeutic strategies. Multiple detection, prevention, and interventional studies have resulted in several treatment strategies of proven benefit. Standard guideline-based therapy for diabetic CKD consists of tight glycemic control, intensive management of hypertension, and aggressive use of renin-angiotensin system (RAS) blockade. Randomized trials have consistently demonstrated the benefit of RAS blockade [particularly with angiotensin-converting enzyme inhibitor (ACEI) and angiotensin receptor blockades (ARBs)] in slowing progression of CKD in both type 1 and type 2 DM.

Nonetheless, the limitations of RAS blockade in diabetic CKD are evident, as the decline in kidney function despite treatment remains higher than that expected due to aging [8]. Meanwhile, concerns remain about the limitations of tight glycemic control, the use of blockade with combinations of RAS medicines, and disappointing development of newer therapies, although increasing evidence suggests that sodium D: glucose D-transporter 2 (SGLT2) inhibitors will help fill that void [9,10]. With or without standard therapy, significant numbers of patients with DM will continue to progress

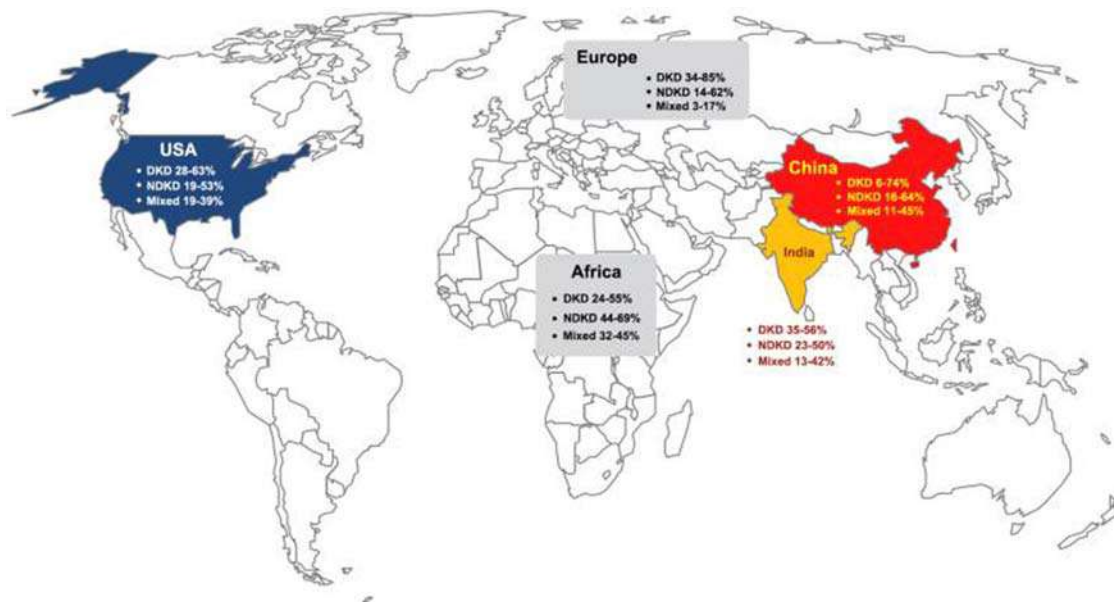

FIGURE 42.1 Diagnostic distributions of diabetic kidney disease, nondiabetic kidney disease, or mixed forms based on diabetes patients biopsied from different institutions worldwide [6].

through the stages of CKD. As diabetic CKD worsens, it becomes more of a systemic disease. When combined, DM and CKD pose a double threat in terms of nutritional and metabolic abnormalities. This chapter presents the pathogenesis and clinical consequences of disorders of nutrition and metabolism in the diabetic CKD patient.

### Glucose/insulin homeostasis

Glycemic management in patients with CKD is complicated by alterations in insulin and glucose homeostasis. Insulin resistance (IR) and glucose intolerance are well-recognized features in patients with CKD. IR may be estimated from fasting glucose and insulin concentrations or determined more accurately by the gold-standard hyperinsulinemic–euglycemic clamp method [11]. Glucose transport is one of the major activities of insulin and is believed to be rate-limiting for glucose uptake in peripheral tissues (Fig. 42.2). The transport of glucose into cells is mediated by specific glucose transporter proteins. Insulin actions at the cellular level are complex but are known to include activation of intrinsic tyrosine kinase activities found in the receptor intracellular beta-subunit portion, intracellular responses, including generation of messengers for insulin, interiorization of the receptor–insulin complex within the cell, translocation of hexose transporter units into the plasma membrane from intracellular storage sites, and the downstream metabolic effects of the hormone [12].

Even nondiabetic CKD patients may have mild fasting hyperglycemia and decreased glucose tolerance [13]. In a recent study of 59 patients with moderate-to-severe nondiabetic CKD, two-thirds had impaired glucose tolerance due to a combination of reduced insulin sensitivity (by hyperinsulinemic–euglycemic clamp) and augmentation of insulin secretion that was inadequate to maintain normal glucose tolerance [14]. Regarding the latter, it has been suggested that urea itself impairs insulin secretion in CKD [15]. Disposal of glucose is inversely related to serum creatinine level [16]. IR may promote kidney disease by impairing renal hemodynamics through mechanisms such as increasing glomerular filtration, activating the sympathetic nervous system, retaining sodium, and decreasing Na,K-ATPase activity [17]. In fact, in a cross-sectional analysis of participants in the Third National Health and Nutrition Examination Survey, Chen et al. reported that IR estimated by the homeostasis model assessment (HOMA) was associated with an increased risk of having CKD [18]. Contributing factors to the abnormalities in glucose homeostasis in people with kidney impairment are shown in Fig. 42.3. Abnormal insulin metabolism involves reduction in renal insulin clearance that is typically present in advanced CKD, stages 4 and 5 [19]. Some evidence suggests that a reduction in pancreatic insulin secretion also occurs, is related to hyperparathyroidism and vitamin D deficiency, and improves with correction of these disorders [20,21]. In a recent clinical report of 120 CKD stages 2 and 3 patients (of whom 19 were being treated for diabetes), 42% suffered from vitamin D

FIGURE 42.2 Schematic representation of the tetrameric insulin receptor and activation of insulin-triggered cellular events in responsive tissues. In activating cellular glucose transport and disposal pathways, insulin first binds to the alpha-subunit of its receptor. Complex effects executed through the insulin signaling pathways and leading to the metabolic actions of insulin are shown.

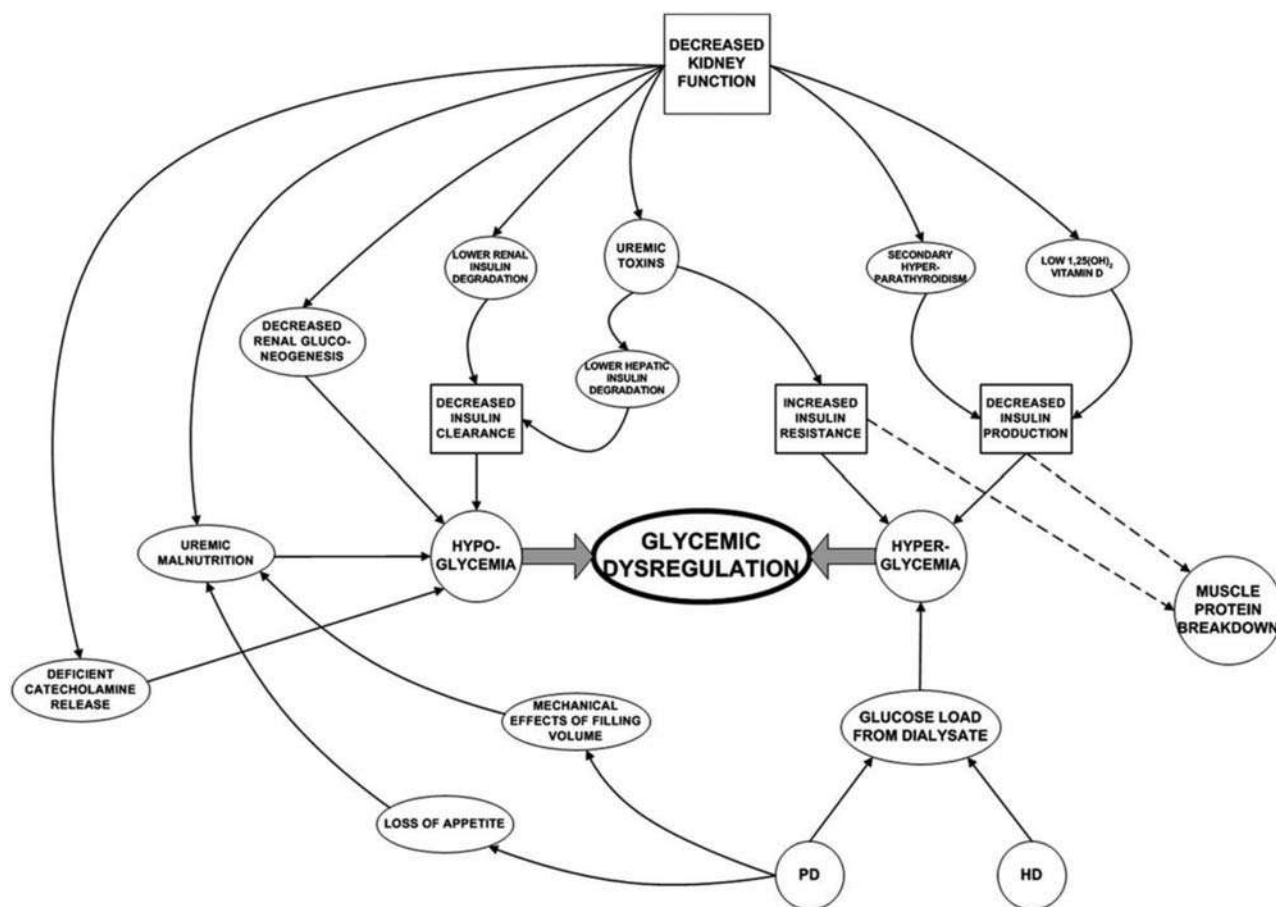

FIGURE 42.3 Overview of glucose/insulin homeostasis in chronic kidney disease/ESRD. Disturbances of glucose metabolism include insulin resistance and glucose intolerance. Several factors contribute to hypoglycemia, which may coexist with hyperglycemia. ESRD, End-stage renal disease; PD, peritoneal dialysis; HD, hemodialysis. Adapted from Kovesdy C, Sharm K, Kalantar-Zadeh K, et al. Glycemic control in diabetic CKD patients: where do we stand? *Am J Kidney Dis* 2008;52:766–77.

insufficiency and 41% were moderately deficient [22]. Research on the metabolic profiles of pancreatic islets during progression of chronic renal failure has suggested that glucose-induced insulin secretion is impaired because of alterations in closure of ATP-dependent potassium channels and reduction in glucose-induced calcium signaling [23]. Other recent research has explored the mechanisms and clinical significance of IR in CKD. It is commonly understood that IR is a characteristic feature of uremia, regardless of the cause of renal disease. In insulin-resistant states, insulin-stimulated cellular glucose uptake is impaired; other insulin actions such as suppression of glycogenolysis, gluconeogenesis, lipolysis and fatty acid release, protein catabolism, and cellular potassium and phosphate uptake may not be similarly impaired [24].

A recent cross-sectional study of 128 diabetic patients from India assessed the degree of IR in those with different stages of diabetic kidney disease (microalbuminuria, macroalbuminuria) as compared to those with normoalbuminuria [25]. IR was calculated using the HOMA method. There was no significant difference between the study groups with regard to age, body mass index, duration of diabetes, or glycemic control. Mean HOMA-IR increased significantly with worsening renal disease ( $P < .0001$ ). In contrast, when 73 nondiabetic CKD patients were evaluated for IR, HOMA-IR did not differ in patients with or without a renal ESRD endpoint, and even after over 24 months of follow-up, the GFR level was not associated with the degree of IR [26]. In reality, IR is somewhat variable in kidney disease, as it is in such other conditions as type 2 diabetes, obesity, or even in normal subjects [27]. Numerous studies suggest that IR in uremia appears to be restricted to defects in glucose uptake and muscle protein anabolism. The ability of insulin to stimulate peripheral glucose disposal by muscle and adipose tissue is markedly impaired, while hepatic glucose uptake is normal and hepatic glucose production is suppressible in uremia [28]. At least two other insulin-mediated effects, its antiproteolytic action and translocation of potassium into cells, are not impaired in advanced renal failure [28,29].

Mechanisms of IR are complex. In general, IR may take the form of defective uptake, metabolism, or storage of glucose in its target tissues (muscle, liver, and adipose tissue) related to alterations in insulin signaling at receptor or postreceptor locations [30]. It is now understood that IR results not from defects in binding of insulin to its receptor on the cell membrane, but to interference with intracellular signaling beyond the receptor [31]. Selective impairment of insulin signaling cascades due to IR may also occur in the kidney [32]. IR in uremia is an acquired defect in the insulin receptor signaling pathway. Stimulation of glucose transport is one of

the major activities of insulin and is believed to be rate-limiting for glucose uptake in peripheral tissues [33]. Central to the biologic actions of insulin, insulin signaling occurs when insulin binds to its receptor, a tyrosine kinase, which then phosphorylates insulin receptor substrates such as IRS1 [34]. Recruitment of multiple downstream targets such as glycogen synthase protein kinase C, endothelial nitric oxide synthase, and others elicit wide-ranging effects, including enhancement of glucose uptake, glycogenesis, lipogenesis, and cellular proliferation [35]. In muscle and adipose tissue, insulin stimulates glucose uptake by promoting translocation of an intracellular pool of glucose transporters to the plasma membrane. Physiological studies have shown that kidney tissues are also responsive to insulin. Moreover, IR in the glomerulus is similar to the IR found in the endothelium of other vascular tissues. This resistance could contribute to the initiation and progression of glomerular lesions in diabetes, in combination with the abnormal pathophysiology in the mesangial cells and podocytes [36]. IR also appears to involve sites distal to the insulin receptor, from the generation of intracellular messengers for insulin [37] to glucose transport to effects of insulin on one of the intracellular enzymes involved in glucose metabolism itself [38].

The mechanisms behind IR in CKD patients are incompletely understood. The improvement in insulin sensitivity associated with dialysis suggests a role for uremic toxins [39,40]. Recent data suggest that alterations in metabolism with CKD may alter adipose tissue secretion patterns independently of obesity. Released adipokines then become an important source of proinflammatory molecules that cause IR [41]. Plasma adiponectin levels are inversely associated with kidney function, and increased adiponectin concentrations may contribute to IR [42]. The production of proinflammatory molecules in adipose tissue may also be modulated by oxidative stress [43]. Yet another factor, erythropoietin deficiency, might contribute to IR. This possibility was suggested by a recent study that showed recombinant erythropoietin-treated hemodialysis patients had lower mean insulin levels and (HOMA-IR) levels than those not treated with erythropoietin [44].

The clinical relevance of insulin and IR in the CKD patient is not fully understood [45]. Renal tissues are responsive to insulin, especially in its renal tubular effects to regulate glomerular endothelial cells [36] and podocytes [46], enhance proximal tubular sodium reabsorption [47], and interact with the renin-angiotensin system [48]. IR promotes kidney disease by impairing renal hemodynamics through mechanisms such as activation of the sympathetic nervous system, sodium retention, increased glomerular filtration, and decreased Na,K-ATPase activity [49]. IR may

contribute to protein-energy wasting, atherosclerosis, and cardiovascular complications in CKD/ESRD patients. One important consequence of IR is protein-energy wasting [50]. Dialysis patients even without DM or obesity have measurable IR associated with increased muscle protein breakdown. Uremic IR contributes to muscle wasting, weakness, and frailty through a form of “bioenergetics failure” involving mitochondrial dysfunction and muscle proteolysis [51]. Muscle protein breakdown in renal failure is at least partly mediated through the ubiquitin–proteasome pathway and is related to suppression of phosphatidylinositol-3 kinase [52,53]. A recent report examined the relationship between HOMA and fasting whole-body and skeletal muscle protein turnover to determine mean skeletal muscle protein synthesis, breakdown, and net balance in nondiabetic chronic hemodialysis patients [54]. An inverse relationship between net skeletal muscle protein balance and HOMA was noted.

Progress in understanding the development of IR in the kidney was recently reported by Mima et al. [36]. These investigators conducted the first comparative analysis of insulin signaling and cellular actions involving the renal glomerulus and tubules; these processes were evaluated in diabetic, insulin-resistant, and control states. It is known that in diabetes, the actions of insulin on the glomerulus may be blunted [35]. After insulin binds to its receptor, downstream targets recruited include Akt, glycogen synthase kinase 3, Ras, extracellular signal-regulated kinase (ERK), and protein kinase C. Activation of these targets elicit wide-ranging metabolic effects. Mima et al. [36] characterized dysfunctional insulin signaling in glomeruli and tubules of diabetic and insulin-resistant animals and suggested that some of these alterations may contribute to diabetic glomerulopathy.

Increased attention has been given recently to the contribution of the kidneys to glucose homeostasis through processes that include renal insulin clearance, as well as gluconeogenesis and glucose filtration and resorption [55]. Roughly a quarter of insulin produced daily by the normal pancreas is cleared by the kidneys, through filtration and tubular secretion, although luminal insulin is so thoroughly taken up by endocytosis that little of the filtered insulin ends up in the urine [33]. However, a much larger portion of administered insulin is renally cleared, as it enters the circulation while bypassing the liver. Normally, up to 180 g of glucose may be filtered each day by the glomerulus, and nearly all of this glucose is reabsorbed in the proximal tubule. This resorption is mediated as secondary active transport through two SGLT proteins. The majority of glucose resorption occurs through sodium D: glucose D-transporter 2 (SGLT2), present in the S1 segment of

the proximal tubule [56]. Increased reabsorption of glucose by the kidneys occurs in type 2 diabetes and is a target of recently developed hypoglycemic agents. Various glucoside compounds have been synthesized that have a high affinity for SGLT2 [57]. Because of their ability to prevent glucose reabsorption and increase urinary glucose excretion, SGLT2 inhibitors have now been approved as an insulin-independent treatment for diabetes [58]. Available information indicates that the administration of SGLT2 inhibitors can induce glucosuria and improve glycemic control in patients with type 2 diabetes without the risk of inducing severe hypoglycemia [59].

### Value of glycemic control and its determination in CKD

The hemoglobin A1c (HbA1c) target and the value of glycemic control in CKD/ESRD continue to be debated. For reasons reviewed next, the benefits of tight glycemic control may be difficult to determine [60]. The previously recommended HbA1c targets in the setting of CKD are in many cases identical to those for the general diabetic population, that is, <7% regardless of the absence or presence of CKD. More recent guideline recommendations have broadened HbA1c targets in the CKD population [61]. Recent observational studies have been consistent in calling into question this approach and established the limitations of HbA1c in advanced CKD while providing somewhat contrasting results and significant methodological differences [62–64]. The single biomarker HbA1c, used in these observational studies, remains the most widely used indicator tool and gold standard of integrated long-term glycemic control in the diabetic population [65]. HbA1c is used clinically to make therapy adjustments and as a marker of risk of complications. For two decades, since the seminal diabetes control and complications trial (DCCT) [66] and United Kingdom prospective diabetes study (UKPDS) [67] demonstrated that HbA1c levels strongly predict the risk of microvascular complications associated with type 1 and type 2 DM, respectively, the glycohemoglobin level has been the primary basis of diabetes management. Indeed, the strength of the association between glycemic control and clinical outcomes is reliant on the relationship between hyperglycemic and elevated HbA1c levels. It has recently been proposed that HbA1c can be used to report estimated average serum glucose levels [68]. HbA1c is a minor component of hemoglobin, comprising about 4% of total hemoglobin in normal adult erythrocytes. The HbA1c level as a marker of hyperglycemia reflects average blood glucose concentration over roughly the three preceding months [69]. Good correlation between HbA1c and blood glucose levels in patients with preserved kidney function has been reported in the

Diabetes Control and Complications Trial [66] and the A1c-Derived Average Glucose study [70]. The American Diabetes Association recommends using point-of-care A1c testing to guide management with a goal of lowering A1c to below 7% [2]. A recent epidemiologic study and an opinion article suggested that HbA1c may be a risk factor for ESRD and mortality in the nondiabetic CKD population [71,72].

However, its unreliability has been recognized in a number of clinical conditions [73], particularly hematologic diseases involving anemia or hemolysis, and has been attributed to the analytical, biological, and clinical variability associated with HbA1c. Analytical variability has resolved with introduction of newer assay methods [74]. Nonetheless, biological and clinical variability of HbA1c continue to limit its application to individual patients, even in the general diabetic population. One source of the variability is differential glycation rates, which appear to vary significantly among individuals. The relationship between HbA1c and time-averaged serum glucose levels also varies across racial backgrounds [73].

More recently, discordances from other measures of glycemic control in clinical studies [75] have raised concerns about the validity of A1c in predicting outcomes in the setting of advanced CKD/ESRD. The Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines for diabetic kidney disease acknowledge that data for validating methods for monitoring glycemia in kidney impairment are severely lacking. For example, a recent United States Renal Data System report indicated that the prevalence of patients with A1c levels over the 7% target was 63% for stages 1 and 2 CKD but fell to 46% in stages 3 and 4 CKD [76], in whom factors such as anemia, typically due to a reduced erythrocyte life span, administration of erythropoietin, blood transfusions, and metabolic acidosis, could affect the reliability of the A1c results [77]. In our large national ESRD database analysis, the mean HbA1c value was only 6.77%, and values over 7.0% were found in only 35% of patients [62]. Unlike the high-performance liquid chromatography assay previously used in routine laboratory A1c testing, the contemporary immunoturbidimetric assay methodology is not influenced by high serum urea nitrogen levels. Nonetheless, A1c may not optimally represent the glycemic state in advanced kidney disease due to the unique changes in physiology. The most cited influences on A1c variability in kidney patients are anemia and the use of erythrocyte-stimulating agents (ESAs). HbA1c indicates the percentage of circulating hemoglobin that has chemically reacted with glucose. Reduced erythrocyte survival in ESRD would be expected to lower HbA1c levels by reducing the time for exposure to ambient glucose [78]. In addition, the

widespread use of ESAs increases the proportion of immature red blood cells in the circulation, with less propensity for glycosylation. One report described a false lowering of A1c with both erythropoietin and darbepoetin analogs in a single patient [79]. As a result, HbA1c levels tend to be lower in diabetic patients with kidney impairment or who are undergoing renal replacement therapy [80]. Peacock et al. measured levels of glycated hemoglobin (HbA1c) and glycated albumin (GA) in 307 patients with diabetes, of whom 258 were undergoing maintenance hemodialysis and the remaining number of patients were without overt kidney disease [80]. In patients undergoing maintenance hemodialysis, the ratios of GA to HbA1c were higher, suggesting that the HbA1c significantly underestimated serum glucose levels. A study by Chen et al. in patients with CKD stages 3 and 4 reported that the mean measured serum glucose levels were about 5%–10% higher than an estimated average glucose (AG) calculated from the same HbA1c, in comparison to the serum glucose in patients with normal kidney function [81]. These findings indicate that the HbA1c underestimates mean blood glucose levels in CKD. A recent small study contrasted 4-day continuous serum glucose monitoring (CGMS) in type 2 diabetic patients undergoing maintenance hemodialysis ( $N = 19$ ) with a larger group of type 2 diabetic patients without nephropathy ( $N = 39$ ) [82]. In all patients the CGMS results and glucose concentrations according to the glucose meter were similar. Glycated hemoglobin and mean glucose concentrations were strongly correlated in the nondialysis group ( $r = 0.71$ ) but were weakly correlated in those undergoing hemodialysis ( $r = 0.47$ ). Hemodialysis patients were receiving erythropoiesis-stimulating agents and had lower hemoglobin levels than the comparator group (11.6 vs 13.6 g/dL,  $P < .0001$ ). These data also indicate that CGMS is a potential tool for understanding changes in glucose homeostasis related to the dialysis procedure itself [83]. A recent review confirmed the inferior correlation of HbA1c with glucose levels in the presence of CKD and emphasized the importance of self-monitoring of blood glucose [84]. Ongoing identifications of sources of variability in HbA1c levels have raised particular concern with regard to relying on this test as the sole measure of glycemia in the diabetic kidney disease population. Fructosamine, a generic test that refers to all glycated serum proteins, is increasingly available for the monitoring of diabetes treatment, particularly for short-term control, but does not correlate strongly with fasting serum glucose levels [73]. Fructosamine is effected not only by protein glycation, but also by the concentrations of individual plasma proteins, which are known to vary in CKD. The need to correct values for total protein or albumin

concentrations remains unresolved [85]. Similar to the HbA1c findings, the study by Chen et al. reported that fructosamine levels were also lower than expected for the same glucose concentration in CKD patients, as compared to patients with normal kidney function [81].

While not as well-studied as HbA1c, evidence has accumulated that measurement of glycated albumin is valuable in assessing glycemic control [86,87]. The clinical usefulness of glycated albumin in CKD was recently reviewed [87]. Relative to HbA1c, GA may more accurately reflect glycemic control in diabetic patients with CKD/ESRD, where HbA1c is particularly unreliable. Albumin undergoes glycation similarly to hemoglobin and accounts for most of the serum glycated proteins. Because the turnover of serum albumin is shorter, (a half-life of approximately 20 days), it reflects a shorter glucose exposure and a potentially more sensitive metric of glycemia. Although not influenced by dialysis or the age or life span of erythrocytes, anemia, or erythropoietin, its precision may be limited in states of abnormal protein turnover, such as from inflammation, hypercatabolic states, peritonea dialysis, proteinuria, albumin infusions, or gastrointestinal protein losses. GA reflects glycemic control for only 1–2 weeks prior to obtaining the sample [88]. In patients with nephrotic proteinuria, GA levels may be falsely reduced. Confounders in GA testing include obesity, smoking, and hyperuricemia, all of which are prevalent in the diabetic CKD population [73]. The case for GA has been bolstered by an improved assay that is unaffected by changes in serum albumin. It has also been suggested that GA *in vivo* has biologic properties that could actually contribute to the pathogenesis of diabetic vascular or other complications [89], as an Amadori-modified reaction product capable of inducing oxidative stress, and enhance proinflammatory endothelial responses in the vessel wall. GA can be measured using a bromocresol purple method and calculated as the percentage relative to total albumin. A reference range of about 12% has been determined for nondiabetic American individuals with normal kidney function [80], with a somewhat wider reference interval compared to the more compressed range of measured values for HbA1c.

GA was deemed superior to A1c in assessing glycemic control in two studies of kidney patients [88,89]. In a large Japanese study of 538 maintenance hemodialysis patients with type 2 diabetes, 828 hemodialysis patients without diabetes, and 365 diabetic patients without significant kidney impairment, Inaba et al. [89] demonstrated significantly lower HbA1c levels relative to blood glucose or to GA levels in patients undergoing chronic dialysis, as compared to those without kidney impairment. The ratio of GA to HbA1c (with a previously reported ratio of approximately 3.0)

was 2.93 in patients without CKD and 3.81 in those undergoing chronic dialysis. HbA1c levels were also higher in patients not treated with ESAs. GA levels were affected by glucose but not serum albumin levels. In a subsequent US study the GA/HbA1c ratio was also significantly higher in ESRD patients (2.72 vs 2.07) [80]. A recent analysis of 24 cross-sectional studies totaling 3928 patients investigated the correlation between GA and HbA1c and AG levels in patients with CKD [90]. The metaanalysis concluded that in the early CKD stages, there was no statistically significant difference between GA and HbA1c, while in advanced CKD, GA was superior to HbA1c in assessing glycemic control. Analysis indicated that in advanced CKD, HbA1c underestimated the glycemic conditions of patients.

Studies to clarify the utility of glycemic control and clinical outcomes in various stages of CKD and in ESRD have emerged. A recent review of randomized clinical trials concluded that patients who received treatment to achieve tighter glycemic control experienced lower risks of new onset microalbuminuria and progression of microalbuminuria [60]. Overall, the effects of tight glycemic control to reduce progression to advanced renal endpoints such as ESRD have been less conclusive. In a population-based cohort study from Canada, Shurraw et al. identified 23,296 people with diabetes and CKD who had baseline HbA1c results [91]. Over a median follow-up of 46 months, 401 developed ESRD. The excess risk associated with higher HbA1c levels varied from 22% (Hgb 7%–9%) to 152% (Hgb higher than 9%) in those with stage 3 CKD, but the corresponding increases were only 3% and 13% in those with Stage 4 CKD. A recent report of 2401 patients demonstrated that higher baseline HbA1c levels were associated with higher risk of renal replacement therapy and all-cause mortality in patients with stages 3 and 4 CKD [92], but not for stage 5 CKD. Secondary analysis of the ADVANCE (Action in Diabetes and Vascular Disease: Preterax and Diamicon-Mr Controlled Evaluation) trial reported a reduced risk for ESRD with intense glucose control [93], while other studies showed no benefit [94]. A recent cohort study of 6165 patients with diabetes and CKD stages 1–5 using HbA1c as categorical and continuous predictor concluded that HbA1c levels were not associated with ESRD risk, although both low and high HbA1c levels increased risk of all-cause mortality [95]. Nonetheless, in a study that focused on 17,819 US Veterans with late-stage diabetic CKD who transitioned onto dialysis, higher mean HbA1c levels ( $\geq 8\%$ ) during the 1-year prelude before ESRD were associated with worse 1-year post-ESRD mortality [96].

A series of studies have addressed the issue of optimal glycemic targets in ESRD [97,98] and suggested

**FIGURE 42.4** Relation of glycemic control and hemodialysis survival among 24,875 hemodialysis patients with follow-up of 3 years, using time-dependent survival models with repeated measures. Data were collected at baseline and every quarter to a maximum of 3 years' follow-up. Extremes of glycemia were weakly associated with survival in the study population [62].

that the overall relationships between glycemic control and survival outcomes are weaker in the presence of ESRD (Fig. 42.4). The use of higher HbA1c targets than for the general diabetes population appears to be preferable in patients with higher levels of comorbidity, according to KDOQI and kidney disease improving global outcomes (KDIGO) clinical practice guidelines [99]. In a large observational study of diabetic hemodialysis patients, only extremes of glycemia (HbA1c <6.5% and >11%) were associated with increased death risk [64]. In a comparably large study with multiple adjustments, Kalantar-Zadeh et al. found that higher HbA1c levels were incrementally associated with higher mortality risk [63]. A smaller but more recent clinic-based study found no association of higher baseline HbA1c with risk of ESRD or death [100].

While many factors in ESRD may conspire to lower HbA1c values, which may only reach >6% in up to one-third of patients [63], some patients have been characterized as having a condition of “burnt-out diabetes,” with spontaneous hypoglycemia and cessation of antidiabetic medications [101], and high risk for poor outcomes, including mortality. A recent study in chronic peritoneal dialysis patients reported that of those identified as “burnt-out diabetes” by HbA1c <6% (21%), the number was reduced by half when a low GA (<16%) was added to the diagnostic criteria [102].

The validity of HbA1c relative to other metrics in ESRD, discussed previously, was evaluated in the GIDE study, which confirmed that HbA1c may be affected by factors not directly related to glycemic control [103]. Analysis of evidence linking serum GA to diabetic ESRD outcomes is now emerging. Freedman et al. [104] determined the association between GA, HbA1c, and serum glucose levels with outcomes (hospitalization, survival) in diabetic dialysis patients (90%

hemodialysis) (Fig. 42.5). Quarterly serum GA levels were measured for up to 2.3 years in 444 prevalent patients. Time-dependent analyses allowed comparisons with available HbA1c and monthly random serum glucose levels. Mean (SD) serum GA was  $21.5 \pm 6\%$  and HbA1c was  $6.9 \pm 1.6\%$ . Increasing GA, but not HbA1c or serum glucose concentrations were predictive of hospitalization and survival. In a large study of 84,282 patients with prevalent diabetes on maintenance hemodialysis, about one-quarter had both GA and HbA1c values [105]. One-year mortality was determined using a Cox regression analysis. Results indicated the superiority of GA over HbA1c in predicting mortality. A recent 2-year nationwide cohort study from Japan in 1601 peritoneal dialysis patients with prevalent diabetes found an association of GA levels >20% and decreased survival, but no association involving HbA1c levels [106].

### Hypoglycemia

Increasing and revived attention is being given to the perils of hypoglycemia (<70 mg%) in the diabetic CKD/ESRD population. The American Diabetes Association recommends a goal HbA1c of <7.0% or as close to normal and as safely as possible without unacceptable hypoglycemia [2]. However, diabetes itself is characterized by acute glucose fluctuations and general glycemic variability (GV). Therefore the regimens used for serum glucose control should be associated with a low risk of hypoglycemia. However, with increasing pressure to achieve tight glycemic control targets, hypoglycemia, in many cases iatrogenic, is becoming more prevalent. In general, the use of insulin secretagogues, missed meals, advanced age, duration of diabetes, and unawareness of hypoglycemia are

**FIGURE 42.5** Relationship between longitudinal measurements of glycated albumin levels and hospitalization rates within 17 days of the measurement in 444 patients with ESRD and diabetes. Higher glycated albumin rates were increased hospitalization and also with poorer survival (not shown) [104]. ESRD, End-stage renal disease.

factors that increase the risk of hypoglycemia [107]. Although hypoglycemia is associated with more intensive glycemic therapy and causes adverse clinical outcomes in patients with diabetes, published reviews on glycemic control in diabetic CKD patients typically include only token mention of hypoglycemia [13]. Increasing attention is being given to the risks of hypoglycemia (below the fasting reference range of about 70 mg/dL) in the diabetic CKD/ESRD population. The altered glucose metabolism in CKD patients poses not only a problem for blood glucose control but also increases the risk of hypoglycemia, which may occur in both diabetic and nondiabetic CKD patients, and which then becomes a deterrent to achieving glycemic control at current target levels for patients with diabetes. The greatest risk of harm is in patients with both CKD and diabetes, particularly in the elderly [108], in whom hypoglycemic episodes may be difficult to diagnose. A large recent population-based study from Taiwan reported a hazard risk of hypoglycemia for CKD in patients with type 2 diabetes of 1.77 [109]. A number of recent reports indicating increased mortality in patients receiving intensive glycemic therapy has driven the renewed interest in hypoglycemia as a marker of adverse clinical outcomes [110]. In settings such as acute myocardial infarction [111] or the intensive care unit [112], enthusiasm for aggressive glycemic control has been tempered by its association with hypoglycemia and worse outcomes. Recent large studies have shown a lack of benefit and sometimes higher risks of morbidity and mortality with tight intensive glycemic control [113], pointing the way toward less intensive glycemic control in at-risk populations. Adverse consequences of hypoglycemia could partially

explain the outcomes from three recent studies, Action to Control Cardiovascular Risk in Diabetes (ACCORD) [114], ADVANCE [115], and veterans administration diabetes trial (VADT) [116], which tried to determine whether diabetes management more aggressive than currently recommended (with a goal of achieving HbA1c levels near 6.0%) would reduce cardiovascular risk in patients with long-standing diabetes. Hypoglycemia occurred more frequently in the intensive therapy arms of all three trials, and in the ACCORD trial, the rate of hypoglycemic episodes requiring medical assistance was three times higher. In ADVANCE, severe hypoglycemia was nearly twice as common in the intensive control group, and half of patients in the low A1c group had at least a minor hypoglycemic event during the study. All three trials failed to demonstrate cardiovascular benefit with such intensive therapy. The ACCORD trial had significantly greater mortality in the intensively treated group and was terminated early because of this higher mortality. This latter group also suffered more hypoglycemia. However, the greater frequency of hypoglycemia in the intensive treatment group was not considered to be the likely explanation for their excess mortality. A subsequent analysis of the ADVANCE trial indicated that severe hypoglycemia constituted an independent cardiovascular risk factor, that is, was associated with increased macrovascular events and death from a cardiovascular cause [117]. Reports on hypoglycemia and kidney disease have generally been limited to case reports, small series, and reviews [118]. In the ADVANCE trial analysis, higher creatinine levels were an independent risk factor for severe hypoglycemia [117]. In patients with uremia, hypoglycemia is more

common than generally appreciated. ESRD unrelated to diabetes is the second most frequent cause of hypoglycemia in hospitalized patients [118] and has a high mortality rate [119]. However, concomitant illness, malnutrition, or drugs commonly contribute to hypoglycemia in these patients [120]. Only one-half of the cases of renal insufficiency and hypoglycemia were diabetic in one study [121]. Mild cognitive impairment, a common problem, particularly in the elderly ESRD patient, may predispose patients to hypoglycemia. In diabetic ESRD patients, glucose levels may be lower during the intradialytic period, and the risk of hypoglycemia is greater during the first 24 hours after a hemodialysis treatment [122].

Epidemiological data regarding the incidence of hypoglycemia among CKD/ESRD patients and on the association between hypoglycemia and overall clinical outcomes have increased in recent years [123]. In one survey, one-half of diabetic chronic hemodialysis patients suffered hypoglycemia over a 3-month period [124]. In a recent CKD report the rate of hypoglycemia within diabetes strata was higher in subjects with CKD, and the risk of severe hypoglycemic events was highest in the group with both diabetes and CKD [122], being roughly twice as high in patients with diabetes who also had CKD versus those who did not. In a recent cross-sectional analysis of adverse events associated with CKD in a large sample size of hospitalized patients with CKD stages 1–4, 2% were due to hypoglycemia [125]. Of note, another recent report using continuous glucose monitoring (CGM) in a modest type 2 diabetes cohort of participants with CKD compared to those without CKD confirmed that hypoglycemia was common but failed to demonstrate a heightened risk related to CKD [126]. The authors concluded that milder hypoglycemia episodes detectable with CGM may not be more frequent related to CKD, but that CKD could increase the likelihood that more severe, clinically apparent episodes are more likely in patients with CKD, as supported by other studies not utilizing CGM.

Aggressive glycemic control in hospitalized patients with CKD may also be associated with increased risk of hypoglycemia without overall improvement in outcomes [127]. A recent report performed a retrospective propensity-matched analysis of patients with diabetes with or without AKI during hospitalization, using a national cohort of US veterans, to determine whether an acute kidney injury (AKI) episode increased risk for subsequent hypoglycemia [128]. After adjustment, AKI was associated with a 27% increased risk of hypoglycemia over 3 months after discharge and varied from 18% (if full renal recovery) to 48% (if no renal recovery).

The pathogenesis of hypoglycemia in diabetic CKD patients is complex and coexists with overall

TABLE 42.1 Factors contributing to hypoglycemia.

<ul style="list-style-type: none"><li>• Poor caloric intake</li><li>• Impaired hepatic glycogenolysis</li><li>• Defective renal gluconeogenesis</li><li>• Diminished counterregulatory response</li><li>• Increased glucose variability</li><li>• Medications</li></ul>
---

disturbances of glucose metabolism in renal failure. As with uremic carbohydrate intolerance, several factors in CKD/ESRD may promote “renal hypoglycemia” (Table 42.1). Anorexia and suboptimal caloric intake lead to reduced glycogen stores. Reduced renal insulin clearance as the GFR falls to 15–20 mL/min/1.73 m<sup>2</sup> results in a prolonged action of insulin. The kidneys are the most important extrahepatic organs for degradation of insulin, and their contribution to insulin removal decreases with declining kidney function. However, insulin levels generally are reported as normal when measured [129]. Insulin, sulfonylureas, and meglitinides are the diabetic agents most likely to be associated with hypoglycemia in the setting of CKD/ESRD. Oral antidiabetic therapies that are renally excreted frequently contribute to hypoglycemia. Insulin doses often need to be reduced by as much as half, especially after dialysis has been initiated, to avoid hypoglycemia. Rapid-acting insulin analogs may be less likely to cause hypoglycemia than regular insulin because the pharmacokinetics are less effected by renal failure [130]. Improved insulin sensitivity may contribute to posthemodialysis hypoglycemia [110]. In addition, the incidence of hypoglycemia may be lower with basal insulin analogs compared to intermediate-acting agents [131], although more sustained if it does occur. The decline in renal mass and impaired kidney function lead to decreased renal gluconeogenesis. During starvation the kidneys become a major source of glucose production through gluconeogenesis from precursor molecules. Deficient catecholamine release in renal failure leads to an impaired counterregulatory response that would normally defend against hypoglycemia. The protective response of glucagon, epinephrine, cortisol, and growth hormone is known to be impaired in DM [132], and deficiencies in glucagon and catecholamines are known to occur in uremic diabetic patients [133]. A case report supported a role for parathyroid hormone in inhibiting insulin secretion in a nondiabetic chronic hemodialysis patient; severe hypoglycemia with endogenous hyperinsulinemia followed parathyroidectomy for severe secondary hyperparathyroidism [134]. Nosocomial hypoglycemia may also occur due to administration of any one of a number of other medications, including  $\beta$ -adrenergic blockers, salicylates, propoxyphene, and sulfonamides [135]. The risk of hypoglycemia may be increased in type 2

patients on sulfonylureas who are treated with antimicrobial agents of various categories [136], for unclear reasons. Preliminary findings suggest that the risk of hypoglycemia is especially high in diabetic ESRD patients who have greater glycemic variability [137].

As noted previously, the health consequences of hypoglycemia can be severe. Glucose is a required fuel for the brain under physiological conditions. Hypoglycemic unawareness may occur. Signs and symptoms, when they do occur, include cold sweats, agitation, dizziness, disorientation, slurred speech, fatigue, altered mental status, including decreased level of consciousness, and seizures. Increased stroke risk may also occur [138]. The occurrence of hypoglycemia complicated by central pontine myelinolysis and quadriplegia has been described [139]. Hypoglycemia, particularly when severe, is a powerful stimulant to the sympathetic nervous system and may cause acute secondary adverse cardiovascular outcomes. The adrenergic response may result in chest pain due to coronary vasoconstriction and ischemia, myocardial infarction, serious cardiac arrhythmias, including QT prolongation and ventricular arrhythmias, and sudden death [140]. While the DCCT clinical trial showed no adverse effects of intensive therapy, without or with severe hypoglycemia, on cognitive status measured objectively over 18 years of follow-up [141], a recent study among elderly type 2 patients with no prior cognitive impairment showed that episodes of hypoglycemia may be associated with increased risk of dementia [142]. The heightened risk of hypoglycemia in the interval before initiation of dialysis, and its effect on outcomes in diabetes patients with declining kidney function transitioning to ESRD was addressed in a recent report [143]. Among 30,156 patients with diabetes and CKD who developed ESRD, the occurrence of pre-ESRD hypoglycemia-related hospitalizations using Cox regression models adjusted for case-mix covariates was associated with higher post-ESRD mortality (hazard ratio (HR) = 1.25), and more frequent episodes had incrementally higher mortality risk.

GV, a measure of volatile glycemic control, is not only a well-established risk factor for hypoglycemia but is increasingly associated with higher independent risk of diabetes-related complications, including mortality. Of note, glucose variability and severe hypoglycemia in ESRD may be associated with higher, not lower, HbA1c values [144]. The use of CGM has led to various operational definitions of GV. These range from basic indices, such as glucose standard deviation, to more complex ones such as mean amplitude of glycemic excursions (MAGE) (the arithmetic mean of the more extreme glycemic excursions) [145]. A recent report utilizing CGM brought attention to the unique problems of GV in acutely ill dialysis patients with

diabetes who were hospitalized [146]. The use of a closed-loop insulin-delivery system resulted in superior glycemic control, including less GV and less hypoglycemia. However, the device requires more thorough validation in this patient population [147].

## Diabetes/bone and mineral metabolism

Epidemiologic evidence and prospective studies have linked vitamin D deficiency to an increased risk of diverse chronic diseases, including autoimmune and cardiovascular disease, cancer, infectious diseases, and type 2 DM [148]. Epidemiologic data also suggest that a significant proportion of cases of type 2 diabetes (the most common form of diabetes) may be attributed to modifiable risk factors related to lifestyle and personal habits [149]. Diabetes is a risk factor for bone loss [150]. Diabetes directly impairs osteoblast function which may lead to decreased bone mass and suppression of bone turnover and impairs bone quality by blunting the secretion of parathyroid hormone. Diabetes also modifies bone collagen through advanced glycation endproducts (AGE) modification [151,152]. Even when bone density in diabetics appears to be similar to that of nondiabetics, diabetic bone may be more fragile [153].

Vitamin D deficiency and insufficiency have been defined as a serum 25-hydroxyvitamin D <20 ng/mL and 21–29 ng/mL, respectively [148]. Data indicate that patients with diabetes have lower serum concentrations of vitamin D than other patients, [154] as well as lower serum intact parathyroid hormone levels [155]. There is little information regarding why DM is associated with low serum vitamin D levels. Recent animal and human studies have provided confirmation that vitamin D might be a potential risk modifier for diabetes [156]; that is, there may be an association between diabetes and vitamin D deficiency. A meta-analysis of five observational studies of vitamin D supplementation in children reported a nearly one-third risk reduction of type 1 diabetes in children who reported ever having received vitamin D supplements [157]. In one study, a low vitamin D status doubled the risk of newly diagnosed type 2 diabetes in elderly patients, after multiple statistical adjustments [158]. An inverse association between vitamin D status and both type 1 and type 2 diabetes has been suggested by some observational studies, whereas other studies on this subject are inconclusive. Based on published data that vitamin D deficiency is associated with impaired B-cell function and IR in animal models and humans, Mattilo et al. evaluated longitudinal data from 4097 adults collected from 1978–80 as part of the Mini-Finland Health Survey [159]. The relative risk of type 2

diabetes between quartiles of vitamin D, after adjustment for confounding factors, was estimated using Cox's model. A significant inverse association was determined between serum 25-OH-D levels and the risk of type 2 diabetes.

To evaluate the association of HbA1c levels with vitamin D status in US adults, Kositsawat et al. analyzed data on 9773 participants in the NHANES 2003–06 [160]. After adjustment for multiple covariates, they observed an inverse relationship between A1c and 25-(OH)-D levels in those individuals who were 35–74 years old. Limited by a single determination of both A1c and vitamin D levels, these cross-sectional results nonetheless suggest a metabolic link between vitamin D concentrations and glucose homeostasis. The authors suggest screening patients with elevated A1c levels for vitamin D deficiency. Data that relate vitamin D and the risk of type 2 diabetes are limited by post hoc analyses and generally inadequate adjustment for confounding variables [161]. The mechanisms by which vitamin D deficiency may cause DM could include increased IR, decreased insulin secretion, and/or autoimmune/inflammatory damage to pancreatic islet cells [156]. A vitamin D receptor and expressible 1- $\alpha$ -hydroxylase are present in pancreatic beta cells. Potential mechanisms whereby vitamin D might affect glucose metabolism by enhancing insulin sensitivity have been recently reviewed [156]. Vitamin D is thought to have both direct (through activation of the vitamin D receptor) and indirect (via regulation of calcium homeostasis) effects on several mechanisms relevant to glucose homeostasis, which could enhance the risk for diabetes in the presence of vitamin D deficiency. A study examined vitamin D status and the relationship between serum 25-(OH)-D concentrations and the components of IR. Insulin sensitivity/resistance was calculated by the quantitative insulin sensitivity check index. Only 17% of subjects had serum 25-(OH)-D concentrations in the recommended range of  $\geq 30$  ng/mL. IR was significantly and inversely correlated with serum vitamin D concentrations [162]. Vitamin D status and IR (by HOMA-IR) were also inversely related in the data obtained from the NHANES III [163]. Although correcting and preventing vitamin D deficiency might have beneficial effects on diabetes and CKD, few prospective trials have been conducted to determine the effects of vitamin D supplementation on IR in CKD patients [164]. Of interest is a placebo controlled 6-month trial of vitamin D3 of 96 participants (randomized, placebo-controlled) with type 2 DM who underwent hyperinsulinemic–euglycemic clamp. The participants on vitamin D had improved peripheral IR and  $\beta$ -cell function [165]. These results suggest that vitamin D3 could improve glycemic control in type 2 DM.

In contrast to observational studies, information pooled from vitamin D interventional trials for the most part appear to be inconclusive [166]. Might vitamin D have a role in reducing the risk of diabetes? The Women's Health Study, for example, suggested a reduction in the development of type 2 diabetes related to a modest increase in vitamin D intake but lacked statistical adjustments [167]. Small doses of vitamin D do not appear to affect measurements of fasting glucose or IR. Vitamin D supplementation in pregnancy or early childhood may reduce the subsequent risk of type 1 diabetes [156]. In one study, Marjamaki et al. reported data from the Diabetes Prediction and Prevention Study, in which the dietary habits of Finnish women were carefully examined and linked to the onset of autoimmunity in their offspring [167]. There was no correlation between the amount of vitamin D consumed by the mother and the appearance of islet autoantibodies in the blood of their offspring in the first postnatal year. Longitudinal observational studies suggest an inconsistent association between vitamin D insufficiency and incident type 2 diabetes [156]. Studies addressing administration of high doses of vitamin D or metabolites with diabetes had been limited to trials involving small numbers of patients or animal studies until recently [168]. An important study published in the *New England Journal of Medicine* in 2019 did address the question as to whether high doses of vitamin D3 would prevent the development of type 2 diabetes [169]. The study enrolled patients thought to be at high risk for the development of type 2 DM and randomized them to 4000 IU/day of vitamin D3—cholecalciferol (2423 participants) or placebo (1211 participants) regardless of their baseline vitamin D level. After a mean follow-up of 2.5 years, there was no prevention effect observed. Perhaps, people with very low levels of vitamin D might have a preventative effect (the average baseline was about 28 ng/mL and rose to 54.3 ng/mL in the treatment group), but routine supplementation for the prevention of type 2 DM cannot be supported at this time.

The active metabolite of vitamin D regulates transcription of multiple gene products, with antiproliferative, prodifferentiative, and immunomodulatory effects. For example, in vitro studies of bone marrow red cell precursor cells demonstrated that 1,25-vitamin D increases Epo-receptor expression [170]. One recent study showed that both 25-vitamin D and 1,25-vitamin D deficiency are associated with anemia [171]. In a study from Denmark, severe vitamin D deficiency was associated with increased all-cause (HR 1.96) and cardiovascular (HR 1.95) mortality [172] in patients with diabetes. Diabetes itself is known to disturb bone metabolism, chiefly in the form of low bone turnover [173], although the relationship between diabetes and

bone disease is complex [153]. Both type 1 and type 2 diabetes are associated with increased bone fragility and a higher risk of fracture. Abnormalities in a number of regulators of bone metabolism have been demonstrated in diabetes that might play a role in the genesis of diabetes-associated osteopenia and reduced osteoblast function. Such abnormalities may include altered vitamin D regulation and relatively low serum parathyroid hormone levels. In cultured bovine parathyroid cells, for example, high glucose levels reversibly suppress parathyroid secretion [174]. Changes in osteoblast phenotype were demonstrated in one recent study, where decreased matrix mineralization was described in bone marrow culture from diabetic mice [175]; this was associated with decreased gene expression of osteocalcin, parathyroid-related protein receptor, the parathyroid receptor, and other factors.

Several studies have demonstrated that calcitriol, paricalcitol, and 1- $\alpha$ -D<sub>2</sub> effectively suppress serum parathyroid hormone (PTH) levels [176]. Tanaka et al. evaluated the impact of diabetes on vitamin D metabolism in predialysis CKD patients by extracting data from over 600 patients (112 of whom had diabetes) in the observational Osaka Vitamin D study [152]. The study reported differences in relevant laboratory measurements (intact parathyroid hormone, 25-hydroxyvitamin D, calcitriol, fibroblast growth factor-23 (FGF-23), calcium, and phosphorus) between 112 diabetic and 112 nondiabetic patients matched for gender, age, and eGFR. Bone mineral density and urinary protein excretion were also determined. No enrolled patient had received vitamin D, bisphosphonates, estrogens, or raloxifene. Mean eGFR was 34.6 mL/min/1.73 m<sup>2</sup> in the diabetic group and 35.6 mL/min/1.73 m<sup>2</sup> in the controls. Corrected serum calcium and serum phosphorus were slightly higher in the diabetes group, while neither PTH nor FGF-23 differed; serum levels of both of these latter hormones increased as kidney function declined. However, diabetic patients had more deficient vitamin D status. Despite similar levels of serum PTH, the diabetes group had lower serum 1,25-D (calcitriol) levels ( $P < .0001$ ) (Fig. 42.6); this difference persisted after multivariate linear regression adjustments for the degree of proteinuria. Low 1,25-D levels in diabetes were related to lower levels of 25-D, its substrate. In diabetic dialysis patients, osteodystrophy is mainly manifested as an aplastic or low turnover type due to low serum intact PTH concentrations. Several vitamin D analogues are available for treatment in CKD patients [177]. Serum PTH levels were affected by the degree of glycemic control in one hemodialysis study, with lower PTH levels in those with poor glycemic control [178]. There are currently no data indicating that the needs for other vitamins or for trace elements for the patient

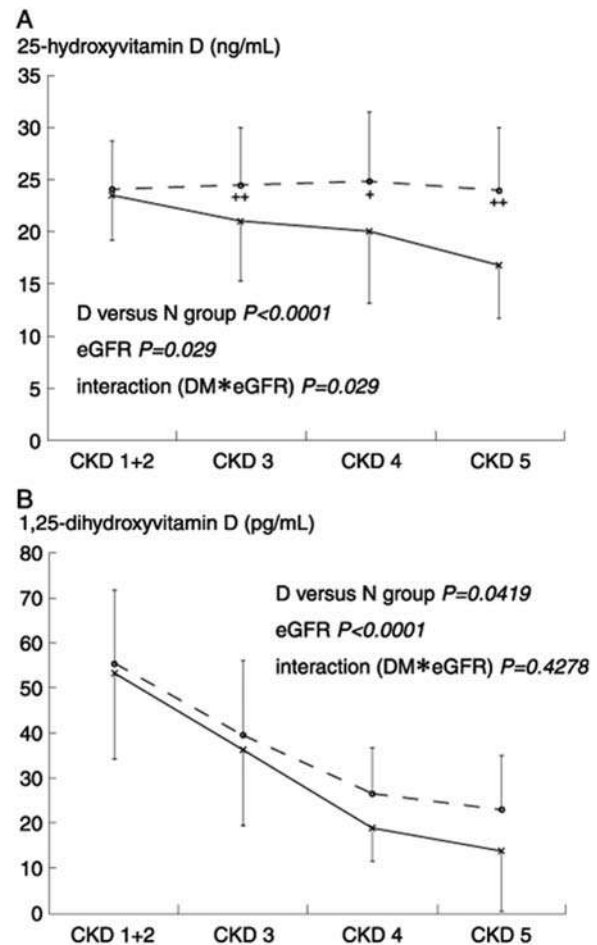

FIGURE 42.6 Impact of diabetes and CKD on vitamin D status in predialysis patients. Differences between the groups were observed in the association between CKD stage and both 25-hydroxy- and 1,25-hydroxyvitamin D. Broken line = nondiabetic, solid line = diabetic. Compared with nondiabetics, diabetic CKD patients had poorer vitamin D status [152]. CKD, Chronic kidney disease.

with diabetic CKD are different from that of CKD patients without diabetic kidney disease who have the same degree of proteinuria.

### Dietary protein intake and diabetic kidney disease

Dietary protein intake has been considered to be an important factor in maintaining kidney health since the last half of the 19th century. There have been many low-protein diets proposed for CKD patients that, initially, were usually aimed at limiting the symptoms of patients with near ESRD and/or reducing the effects of azotemia. Some of the early studies were also designed to reduce progression of CKD. An article by Giordano in *Kidney International* [179]

described the work in 1923 of F.M. Allen at the New England Deaconess Hospital. Dr. Allen did studies to determine the feasibility of a very-low-protein diet initially by feeding a medical student a diet of 4000 calories for 24 days that consisted of carbohydrates and fats (and only 300 mg of protein/day). The urine urea nitrogen excretion dropped from 14.25 to 1.58 g/day. Apparently, the medical student stopped the study earlier than Dr. Allen because the student feared for his health and had distaste for the very-low-protein diet. Dr. Allen followed up that study by administering a diet of 18 grams of protein/day to a 70-kg azotemic patient (0.26 g/kg) for 6 months. The diet successfully lowered nitrogen waste excretion but was extremely hard to maintain.

The contemporary approach to the utility of low-protein diets derives primarily from work from the 1970s to 1990s. Low-protein diets have been used for two major goals: (1) to slow the decline in GFR and (2) to ameliorate signs and symptoms of patients with near ESRD. But are low-protein diets effective? Seminal work from this time period was done in Munich-Wistar rats that have their glomeruli near the cortical surface thus making them accessible for micropuncture studies [179–185]. Using tiny glass pipettes, researchers measured glomerular pressures (including transcapillary pressure,  $\Delta P$ ) and GFR as well as afferent renal blood flow,  $Q_A$ ). The value of this animal model is that very exact, detailed readings could be obtained from single nephrons. As most models of kidney failure take a long time to develop, rat models were designed to accelerate the rate of decline in GFR. These models included various degrees of removal of kidney tissue such as the one and two-thirds nephrectomy model where the rat was left with only one-third of one kidney. Other models consisted of altering the protein in the diet and/or making the animals diabetic.

A landmark paper published by Zatz et al. provided a hemodynamic explanation for declining GFR and a pathophysiologic rationale for limiting protein in the diet in patients with diabetic kidney disease [185]. Rats were maintained for 1 year on a 6% protein diet (low protein), 12% protein diet (normal rat diet), or 50% protein diet (high protein). In addition, half of the rats were made diabetic. Rats were studied at 2–10 weeks for micropuncture studies and at 11–13 months for pathology. Fig. 42.7 shows the essential findings that as protein intake increased there were increases in single-nephron GFR (SNGFR) and increases in  $Q_A$  and  $\Delta P$ . Animals that were diabetic had even greater increases in SNGFR,  $Q_A$ , and  $\Delta P$ . And the combination of a high-protein diet and diabetes engendered the greatest increase in all of these parameters. Importantly, the rats maintained on the low-protein diet (diabetic or not diabetic) showed no changes in these parameters as compared to nondiabetic control rats on a normal 12% diet. Urinary albumin excretion was also studied. The data revealed that the diabetic rats fed a high-protein diet developed especially high levels of urinary albumin, whereas the rats fed the low-protein diet had normal levels of urinary albumin, whether or not they were diabetic (Fig. 42.8). Examination of the kidney pathology consistently revealed a lesion of secondary focal and segmental sclerosis in the rats that had increased glomerular pressures, blood flow, and increased urine albumin levels as compared to the rats with normal glomerular pressures and blood flow. Thus the hypothesis for progression of diabetic kidney disease was proposed, stating that glomerular hyperfiltration/hypertension leads to progressive sclerosis of glomeruli and loss of GFR and interventions that prevent these hemodynamic changes should slow or prevent the decline in GFR. Hence, low-protein diets should effectively slow progression by lowering intraglomerular pressures and blood flow rates. These

FIGURE 42.7 Munich-Wistar rats were treated with three different diets as noted previously and were either nondiabetic or diabetic (by injection of streptozotocin). After 2–10 weeks, micropuncture studies were performed. Both increased dietary protein and diabetes led to increased glomerular flow rates (SNGFR), afferent renal arteriole blood flow rate ( $Q_A$ ), and intraglomerular pressure ( $\Delta P$ ). The combination of high protein and diabetes had the greatest increases in these hemodynamic parameters [186]. SNGFR, Single-nephron glomerular filtration rate.

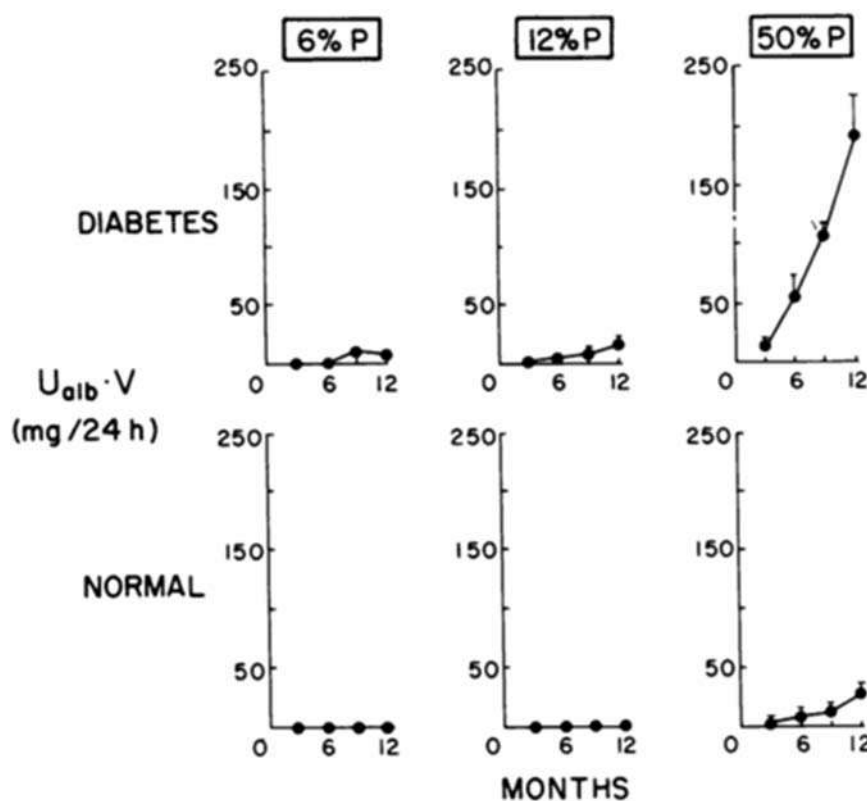

FIGURE 42.8 Munich-Wistar rats were treated with three different diets as noted previously and were either nondiabetic or diabetic (by injection of streptozotocin). Dietary protein percentages are shown at the top of the graph. Urinary albumin excretion rates were followed over time. The combination of diabetes and 50% protein diet had the greatest effect on increasing urinary albumin excretion rate [186].

results provided very compelling arguments for human studies to test the value of low-protein diets for slowing progression of diabetic kidney disease.

Although these physiological studies appear to be convincing, there are concerns as to the interpretation of results, which are as follows. First, the measurements in these models were from a very small number of nephrons and may not reflect hemodynamics in the kidney as a whole. Second, of necessity, the micropuncture studies were a snapshot in time and may reflect only the hemodynamics of that time period but not necessarily reflect the hemodynamics over an extended period of time. Indeed, the micropuncture measurements were done at 2–10 weeks after the creation of diabetes, whereas the increases in urine albumin level did not occur until months later. And the pathology was examined 10–12 months after the micropuncture studies. Moreover, these results indicate that glomerular hyperfiltration per se is deleterious; yet, to date, there is no convincing evidence in humans that prolonged glomerular hyperfiltration does predict declining GFR. Third, there is the usual concern that animal models do not reflect human disease, nor do they necessarily reflect the response to treatment in humans. Nevertheless, important studies such as Zatz et al. and others have provided the basis for the hypothesis that a critical component of treatment

of patients with diabetic kidney disease is to lower the intraglomerular pressures or flows [179–185]. Hence, the presumed efficacy of low-protein diets is to lower intraglomerular pressures and flows. Since angiotensin II is the major regulator of intraglomerular pressures by causing vasoconstriction, preferentially in the efferent arteriole, studies have been conducted using inhibitors of angiotensin II. In a subsequent paper, Zatz et al. used the ACEI enalapril in the same diabetic rat model that the protein studies were done and showed that enalapril reduced glomerular pressures, lowered urine albuminuria, and ameliorated the deleterious effects of diabetes on rat kidneys [184]. Since then many human studies have proven that agents that block the actions of angiotensin II successfully slow progression of diabetic kidney disease in patients who have increased levels of urine albumin level. These medicines include the ACEIs, angiotensin receptor blockers, and renin inhibitors [186]. Interestingly, for these medicines there is evidence that there is a hemodynamically mediated decrease in GFR that is necessary for optimal efficacy of these agents. For example, in the reduction of endpoints in NIDDM with the angiotensin II antagonist losartan (RENAAL) study in which diabetic patients were treated with or without the ARB, losartan, the results demonstrated that the greater the initial decline in GFR in patients treated with losartan, the slower the

subsequent rate of decline in GFR. [187–188]. Of note, these studies do not prove that decreases in GFR are mechanistically important for the effect of losartan for slowing the decrease in GFR; this reduction in the decline in GFR may just be a marker of drug effect.

Since the early 1980s there have been many small studies that suggested that low-protein diets were effective in slowing progression of diabetic kidney disease. However, the largest and most influential study on the effect of low-protein diets on the progression of kidney disease had very few diabetic kidney disease patients. The Modification of Diet in Renal Disease (MDRD) study that was published in 1994 [189] followed two groups (the mean follow-up was 2.2 years)—one with GFRs between 25 and 55 mL/min (585 participants—who were randomly assigned to a “normal” protein diet providing 1.3 g/kg/day or a low-protein diet containing 0.58 g/kg/day) and a second group with more advanced kidney disease who had GFRs between 13 and 24 mL/min (255 participants) and who were randomly assigned to diets providing either 0.58 or 0.26 g/kg/day (with supplementation with some essential amino acids and ketoacid analogs of other essential amino acids). The results did not show a beneficial effect of low-protein diets on slowing progression of renal disease. There was also a low versus normal blood pressure arm of this study. As has been shown by many studies, blood pressure control had a significant effect on slowing a decline in GFR. Only 3% of the participants had diabetes and all of these people had type 2 diabetes as the researchers excluded any patients who were taking insulin. Thus this study did not adequately determine whether diabetic kidney disease patients would have benefit from a low-protein diet. But the negative results of the MDRD led to much decreased enthusiasm for routine use of low-protein diets. In 1999 many of the authors of the original study wrote a retrospective review arguing that at best this study was inconclusive and that there were trends toward better outcomes in patients who were assigned to the low-protein diet [190]. Moreover, several problems were inadvertently incorporated into the experimental design of the MDRD study. These are discussed in Chapters and might account for the inconclusive results of this trial. Thus it has been argued that a low-protein diet should still be considered for patients with CKD. Interestingly, the achieved protein diet (as measured by 24-hour urine protein excretion) in the low-protein diet group (0.58 g/kg/day) was about 0.77 g/kg/day, almost the same as the recommended protein intake for diabetic patients by the American Diabetes Association of 0.8 g/kg/day [191]. So the argument as to whether diabetic kidney disease patients should be treated with a low-protein diet might well be a moot one. However, some workers in this field do

recommend substantially lower protein diets for CKD patients.

In 1997 the EURODIAB IDDM trial was published [192]. In this study, 2696 type 1 diabetic patients in 30 countries had their dietary history taken and laboratory values measured. The results showed that patients who had <20% of their calories from protein had lower levels of urinary albumin excretion as compared to those patients who reported >20% of their calories from protein. The study appeared to show that as dietary protein increased there was a gradual and significant increase in urine albumin excretion. But the participants with higher urinary albumin excretion also had worse glucose control (as measured by higher glyco HbA1c) and higher blood pressure. In fact, the combination of increased A1c and increased blood pressure was the strongest predictor of high urinary albumin excretion rates, suggesting that protein intake was much less important. Another study published in 2007 from the ERIKA Study group evaluated three diets: very low protein (0.35 g/kg/day), low protein (0.6 g/kg/day), and a free diet (*ad libitum* protein intake) in patients with stages 4 and 5 CKD [193]. There was significantly lower urinary protein excretion in the very-low-protein diet group after 6 months of dietary treatment and not in the other two groups. But it was also noted that the salt intake (as measured by urine sodium content) decreased significantly as protein content in the diet decreased. This suggests the possibility that the decrease in dietary salt intake led to a decline in blood pressure as the main reason for the observed reduction in urine protein level. Indeed, the mean blood pressure in the very-low-protein group was 143/84 mmHg at the beginning of the study and decreased to 128/78 after 6 months. The authors concluded that factors other than the amount of protein ingested were responsible for the decrease in urine protein excretion. In 2009 the Cochrane Reviews performed a detailed analysis of randomized controlled trials in patients with diabetic kidney disease [194]. The authors' conclusions were that at that time there was little published evidence that low-protein diets were of benefit for CKD patients. The protein content of the low-protein diets in the reviewed studies was not very low, between 0.6 and 0.8 g/kg/day, and the sample size of the studies evaluated was often relatively small. Hence, it could be argued that this Cochrane Review of low-protein diets for diabetic CKD is not definitive.

None of the studies convincingly showed an effect of low-protein diet on slowing progression of kidney disease in patients with diabetic nephropathy. It is our conclusion that at this time there is no convincing evidence that a low-protein diet is of benefit in patients with diabetic kidney disease. As the current

recommendation for dietary protein for diabetic patients is routinely in the 0.8–1.0 g/kg/day range, a low-protein diet needs to be less than this. There is not enough evidence for a beneficial effect of protein diets of <0.6 g/kg/day for diabetic patients with CKD, and many studies, including the MDRD study, suggest that it is difficult to maintain protein diets at 0.6 g/kg/day or lower. On the other hand, the data are insufficient to prove that low-protein diets do not retard progression of CKD. Thus for diabetic CKD patients who are willing to try protein intakes in the range of 0.6 g/kg/day or very-low-protein diets (about 0.3 g/kg/day) supplemented with ketoacid/essential amino acid mixtures, it can be argued that they should not be discouraged from doing so (please see Chapter).

Another issue is the adherence to a low-protein diet. A recent 2-year study from Italy showed that adherence to a low-protein diet can be relatively high [195]. A total of 422 participants with stages 3–5 CKD were enrolled. The baseline diet was 0.59 g/kg/day and 6 months later the average protein intake was 0.72 g/kg/day). Two-thirds of the participants were still on the diet with the main reason for dropout being dialysis or death. Quality of life measures showed that the participants were satisfied with the diet. An excellent editorial about the study [196], notes that even though the diet was well tolerated, it needs to be individualized. That is, patients where malnutrition is a concern should not be placed on a low-protein diet. The risks clearly outweigh the benefits. The authors of the editorial also wrote an interesting overview of vegetarian diets and CKD [197]. They are clearly in favor of vegetarian diets as they seem to have similar benefits to low-protein diets in that a vegetarian diet may lead to lower blood pressure, less inflammation, and less oxidative stress. But there is very little evidence at this time that a vegetarian diet per se is renoprotective.

So does the source of the protein make a difference? There are only limited studies on this issue. For example, Knight et al. studied changes in estimated GFR in 1135 participants with GFR > 80 mL/min and in a second group of 489 participants with GFR between 55 and 80 mL/min from the Nurses' Health Study [198]. Only a small percentage of the subjects had diabetes. The groups were subdivided into protein intake that was primarily nondairy animal protein, dairy protein, or vegetable protein. The participants taking the vegetable protein had either no decline or the slowest decline in GFR as compared to the other groups. It is relevant that this study evaluated dietary intake of protein only twice via questionnaires, in 1990 and 1994. Thus the reliability of the findings is brought into question by the limited frequency of data measurements in the same subjects. Another study (albeit one with only 300 patients) examined whether eating

primarily fish protein was beneficial [199]. The authors noted that a high intake of fish protein significantly slowed the development of microalbuminuria in type 1 diabetic patients. These results are interesting but in and of themselves do not present a clear diet plan that should be prescribed for patients with diabetic kidney disease.

Lastly, the onset of end-stage kidney disease significantly changes the protein intake recommendations. Protein-energy wasting is a well-documented, important issue in dialysis patients that needs to be properly assessed and treated to prevent significant malnutrition. National Kidney Foundation guidelines recommend an intake of 1.2 g/kg/day for hemodialysis patients and 1.3 g/kg/day for peritoneal dialysis patients [200]. The recommendations for protein intake are higher in dialysis patients than nondialysis patients due to a combination of such factors as increased catabolic rates in dialysis patients, removal of nutrients during dialysis, effects of bioincompatible materials, and others [201]. Moreover, there is a close association of protein wasting with inflammation, strongly suggesting that proper protein intake is needed to limit the inflammatory state of dialysis patients [202]. An interesting retrospective analysis of 53,933 patients undergoing maintenance hemodialysis examined the relationship of mortality and protein intake by evaluating the relation between urea kinetic-based normalized protein nitrogen appearance and all-cause and cardiovascular mortality over a 2-year period [203]. Dialysis patients who ingested <0.8 or >1.4 g/kg/day had significantly higher mortality rates. The best survival was associated with a protein intake of 1.0–1.4 g/kg/day. The risks of protein and energy wasting are more pronounced in patients who also have diabetes possibly due to the effects of diabetes on metabolism, decreased effects of insulin, and/or IR as well as to comorbid conditions such as hypertension and vascular disease [204]. Hence, when diabetic patients approach end-stage kidney disease (at CKD stage 5), nutritional assessment should be conducted to provide optimal protein and calorie intake to prevent wasting and reduce inflammation.

### Salt intake and diabetic kidney disease

The link between salt intake and hypertension has been established over many years of research. There is no question that in patients who are salt-sensitive, limiting salt intake will lead to lower blood pressure and as a result improved long-term outcomes (please also see Chapter). A 2010 Cochrane Review evaluated 818 studies related to reducing salt intake and progression of diabetic nephropathy and concluded that there was

strong evidence for limiting sodium chloride intake to at least less than 5–6 g/day [205]. But the authors noted that there are relatively few well-controlled studies that specifically target salt intake independently of other variables, and that many studies are of short duration or use wide variations in sodium intake. Nevertheless, the current recommendation is to limit sodium chloride intake to help lower blood pressure, as lower blood pressure is clearly beneficial in slowing or even preventing progression of CKD. Moreover, salt intake needs to be limited in patients taking diuretics or the effect of the diuretic will be greatly diminished.

But is there a unique role for salt intake in the progression of diabetic kidney disease? It has been well established that diabetic kidney disease is associated with activation of the renin–angiotensin–aldosterone system (RAAS) [206,207]. Elevated levels of angiotensin II will lead to enhanced proximal reabsorption of sodium and elevated levels of aldosterone will lead to enhance collecting duct reabsorption of sodium. There are very few studies addressing the role of limiting salt intake in patients on specific medications. For example, Bakris and Smith evaluated the role of sodium intake on albumin excretion in diabetic nephropathy patients taking either the dihydropyridine calcium channel blocker, nifedipine, or the nondihydropyridine calcium channel blocker, diltiazem [208]. As previously observed, diltiazem led to a decrease in urinary albumin excretion whereas nifedipine did not. And a lower sodium chloride intake enhanced the effects of diltiazem on lowering the urinary albumin excretion. A similar study was done in patients who were treated with the angiotensin receptor blocker, losartan [209]. The authors reported that the achieved mean urinary sodium excretion on a low-sodium diet was 85 and 80 mmol/day in the losartan and placebo groups, respectively. In the losartan group the additional blood pressure–lowering effects when patients ingested a low-sodium diet, as compared to a regular sodium diet, for 24-hour systolic, diastolic, and mean arterial blood pressures were 9.7, 5.5, and 7.3 mmHg, respectively. In the losartan group the urinary albumin to creatinine ratio decreased significantly on the low-sodium diet as compared to the regular-sodium diet, and it was strongly associated with a decrease in blood pressure. These studies are illustrative of other reports in the literature. A more recent small study (89 participants with diabetic kidney disease) from Holland showed that a very low salt intake (average 393 mg/day) was effective in lowering blood pressure and albuminuria by enhancing the effects of RAAS inhibitors [210]. And a recent metaanalysis of salt intake and CKD also supported the use of at least moderate salt restriction [211]. An interesting study from South Korea though evaluated salt

intake in incident CKD patients [211] and found that both high ( $>4.03$  g/day) and low salt intake ( $<2.08$  g/day) was associated with worse outcomes (development of incident CKD as defined as an  $\text{eGFR} < 60$  mL/min). But this association was only seen in participants with hypertension. This study is interesting as it included about 8000 participants over a 10- to 12-year follow-up. About 20% had diabetes. It is not clear if this study is generalizable. But it certainly is another example that dietary intervention always needs to be individualized. At this time though, the recommendation is that for hypertensive patients with diabetic kidney disease, it is prudent to limit salt in the diet to lower blood pressure, to enhance the effects of various antihypertensive and diuretic medications, and to improve cardiac outcomes [212].

Fructose is a simple sugar that is the primary nutrient in fruits and honey, which are classically considered healthy foods. Fructose is also a major component of refined sugar, which has classically been viewed as a nonnutritional food or “empty calorie.” In the last decades the viewpoint that fructose is simply a caloric source of nutrition has shifted to one that places it at the top of the list for driving diseases such as obesity and diabetes. The new studies have raised important questions related to the optimal diet for subjects with chronic or end-stage kidney disease, in which historic recommendations focused primarily on a restriction of proteins (especially red meats) and high-fat diets. Here we both review the role of fructose in the subject with chronic kidney disease (CKD) and also make recommendations for management.

## Sources of fructose

Fructose is the primary nutrient in fruits and honey and is responsible for its sweet taste. While this was the main dietary source of fructose for most of human history, the introduction of refined sugar from sugarcane, sugar beets, and palm trees led to a major increase in fructose intake, as sugar consists of a disaccharide of fructose and glucose. The intake of sugar rocketed from around 3 pounds per capita per year in 1700 to more than 150 pounds in 2000. Refined sugar caused a massive increase in the intake of sweets and desserts and was also commonly added to alcohol and other foods, with its largest source being soft drinks.

One problem with sugar is that it crystallizes easily, making it difficult to mix with many foods. A solution occurred in the 1970s when high-fructose corn syrup (HFCS) was introduced. Corn contains primarily dextrose (glucose), but a method was developed to convert glucose to fructose using an isomerase enzyme. This allowed a cheap source of fructose that could then be mixed with glucose as a combination of free monosaccharides, often containing 55% fructose and 45% glucose, which was found to be an optimal taste that consumers like. Advantages of HFCS include less crystallization at lower temperature, which is useful for frozen food such as ice cream, and an improvement of product flavor with browning development under heat in the Maillard reaction, in which fructose nonenzymatically binds to damaged lipids, protein, and DNA.

While sugar and HFCS are the primary sugars added to soft drinks and desserts, they are also often added to other foods. Today about 70% of processed foods contain these added sugars, and they are also a principal ingredient in most baby foods [1,2]. Currently, sugar represents approximately 15% of the normal diet, and in some groups (adolescents and ethnic minorities) the intake of sugar may reach 25% or more [3]. Importantly, trends are changing, and since 2008, there has been a progressive decrease in the intake of soft drinks containing sugar, although this has been countered to some extent by intake of sports drinks, energy drinks, and other sugary beverages [4].

Unfortunately, we are not only obtaining fructose from our diet. While dietary fructose is likely our primary source of fructose, fructose can also be endogenously

TABLE 43.1 Conditions that stimulate endogenous fructose production.

Mechanism	Associated conditions

produced under several conditions (Table 43.1). The sole mechanism for generating fructose in humans is via activation of the polyol pathway that converts glucose to fructose by sequential enzyme reactions, beginning with aldose reductase that converts glucose to sorbitol, followed by the conversion of sorbitol to fructose via sorbitol dehydrogenase. One of the best known mechanisms for generating fructose is the diabetic state, as hyperglycemia is well known to stimulate aldose reductase and induce the production of sorbitol and fructose [5].

However, there are other stimuli that activate the aldose reductase pathway. One of the most important ways is by eating fructose itself, possibly by the generation of uric acid that occurs during its metabolism [6]. Alternatively, hypoxia stimulates aldose reductase and endogenous fructose production, which has been shown in ischemic disease of the heart and kidney where the fructose has been shown to play a role in the injury [7,8]. Hyperosmolarity is another major stimulus for aldose reductase synthesis and activation, and fructose can be generated in the hypothalamus and kidneys in the setting of dehydration, where it has been shown to stimulate vasopressin release and induce kidney damage [9,10]. Recently, diets high in salt have been found to induce endogenous fructose production in the liver through its effect on raising portal vein osmolality stimulating the polyol pathway, with effects similar to that observed with dietary fructose intake [11]. The observation that hyperosmolarity is a stimulus for fructose generation is of concern in the patient with end-stage kidney disease in which hyperosmolarity is common.

Metabolism of fructose

In many respects, fructose appears very similar to glucose, and much of the metabolism of fructose and

glucose is similar, especially following the first few steps in metabolism. However, fructose appears to be unique from glucose and most nutrients in its ability to induce obesity and diabetes. For certain, other components of the diet [such as *trans* fats, omega-6 fatty acids, and alcohol (especially beer)] may increase the risk for metabolic syndrome, but fructose appears to be especially capable of inducing features of metabolic syndrome. This appears to be due to its unique ability to reduce intracellular energy levels before it generates energy.

The intake of sugar (sucrose) results in its rapid breakdown in the gut by sucrase to generate the monosaccharides glucose and fructose. Fructose is then taken up by the specific glucose transporter 5 (Glut5) in the small intestine [12] where some of the fructose is metabolized [12]. However, as concentrations of fructose increase, the intestinal metabolism becomes saturated resulting in significant delivery of fructose to the liver via the Glut2, with the remaining 20%–30% of fructose being taken up by the kidney, adipose tissue, and other organs [13,14].

While fructose can be metabolized by hexokinase, most of the fructose is metabolized by fructokinase (ketohexokinase, KHK), which phosphorylates fructose to fructose 1-phosphate (Fig. 43.1). There are two isoforms of fructokinase, with fructokinase C (KHK-C), being the major isoform in the liver, and KHK-A isoform being more ubiquitously expressed. KHK-C is a rapid phosphorylator whereas KHK-A only slowly metabolizes fructose. Indeed, it is the KHK-C that appears to be the key enzyme driving the metabolic effects of fructose [15]. This is because the metabolism of fructose by KHK-C reduces the energy in the cell.

KHK-C is poorly regulated, and when it metabolizes fructose there is an immediate decrease in intracellular phosphate, adenosine triphosphate (ATP), and guanosine triphosphate (GTP) levels, leading to transient inhibition of protein synthesis and an accumulation of adenosine monophosphate (AMP) [16]. The decrease in intracellular phosphate stimulates activation of AMP deaminase, resulting in the generation to inosine monophosphate and eventually uric acid [17,18].

While uric acid is considered to be an antioxidant in the extracellular environment, when uric acid is produced intracellularly, it stimulates intracellular oxidative stress via activation of Nicotinamide adenine dinucleotide phosphate (NADPH) oxidase that is then translocated to the mitochondria, where it blocks mitochondrial ATP production by interfering with beta-fatty acid oxidation [19–21]. Fat synthesis is stimulated in association with endoplasmic reticulum stress, stimulation of transcription factors of sterol regulatory element-binding protein- $\alpha$ , and generation of citrate

**FIGURE 43.1** *Fructose metabolism:* In the classic “caloric” pathway, fructose is metabolized to fructose 1-phosphate followed by its metabolism by aldolase B and other enzymes, eventually generating the acyl glycerol, diacylglycerol, with the formation of glucose, lactate, glycogen, and triglycerides. The adenine nucleotide degradation pathway is associated with the stepwise reduction of ATP to uric acid. Most evidence suggest that this latter pathway is responsible for metabolic alterations, including mitochondrial oxidative stress, AMPK inhibition, leptin and insulin resistances, obesity, diabetes, systemic/glomerular hypertension, vascular diseases, and renal tubular injury with phenotypic changes. *AldB*, Aldolase B; *AMPD*, AMP deaminase; *AMPK*, AMP-activated protein kinase; *DHAP*, dihydroxyacetone phosphate; *Fru 1 P*, fructose 1-phosphate; *Fru1,6P<sub>2</sub>*, fructose 1,6 bisphosphate; *G3P*, glyceraldehyde 3-phosphate; *KHK*, fructokinase; *low Pi*, low level of intracellular phosphate.

[21,22]. A stimulation of glycolysis also occurs, resulting in a persistence of the low energy state [23]. Consistent with activation of these pathways, the ingestion of fructose results in an acute increase in intracellular uric acid in the liver with release into the circulation. Intracellular uric acid increases, releasing uric acid into the circulation by 1 to 2 mg/dL that peaks 15 minutes to an hour after ingestion [24,25].

In contrast, when glucose is metabolized, the initial phosphorylation by glucokinase is tightly regulated such that intracellular levels of ATP do not fall, AMP accumulation does not occur, and activation of AMP deaminase is prevented.

Thus there are essentially two pathways of fructose metabolism by KHK-C. The first pathway is the classic “caloric” pathway in which fructose is metabolized to fructose 1-phosphate followed by its metabolism by aldolase B and other enzymes, eventually generating the acyl glycerol, diacylglycerol, with the formation of

glucose, lactate, glycogen, and triglycerides. The second pathway is the adenine nucleotide degradation pathway associated with the stepwise reduction of ATP to uric acid (Fig. 43.1). Most evidence suggest that it is this latter pathway that is responsible for how fructose induces metabolic syndrome.

### Fructose as a potential cause of hypertension, obesity, and metabolic syndrome

#### Experimental studies

Several investigators have demonstrated that rats on high-fructose diet, but not on glucose, developed features of metabolic syndrome, including hypertension, insulin resistance, and hypertriglyceridemia [26–29]. Mice also develop features of nonalcoholic fatty liver disease (NAFLD) and metabolic syndrome with fructose, although this occurs better if the fructose is provided in the drinking water [30]. This is likely due to the fact that liquid sugars result in both a greater load and faster absorption that results in higher concentrations of fructose in the liver, leading to more profound ATP depletion with greater activation of the adenine nucleotide degradation pathway [4]. The importance of the fructose pathway is further illustrated by the observation that mice fed a Western diet high in sugar and fat develop severe fatty liver and insulin resistance that is markedly less in mice lacking fructokinase [15].

#### Clinical studies

Fructose also drives obesity and metabolic syndrome in humans. In 2009 Stanhope et al. reported that the administration of fructose in beverages providing 25% of energy requirement for 10 weeks resulted in reduced insulin sensitivity, dyslipidemia, increased visceral adiposity, and enhanced hepatic lipogenesis that was significantly greater than that observed in control subjects given glucose [31]. A randomized controlled trial also demonstrated that only 2 weeks of fructose administration could induce many features of metabolic syndrome in men [32]. Subsequently, an interventional study by Lustig et al. found that isocaloric fructose restriction could improve features of metabolic syndrome in children [33]. Likewise, 8 weeks of provision of a diet low in free sugar content compared with usual diet significantly improved steatosis in the adolescent boys with NAFLDs [34].

### Fructose as a mediator of kidney diseases

The possibility that fructose may play a role in the development of kidney disease is increasingly likely,

given its potential role in driving hypertension and diabetes as well as well-known association between metabolic syndrome and CKD. Furthermore, there is some evidence demonstrating the role of fructose in tubulointerstitial fibrosis, glomerulosclerosis, and renal microvascular disease [35–38].

## Experimental studies

The administration of fructose (60% diet) induced renal hypertrophy with tubular cell proliferation and low-grade tubulointerstitial injury, generating chemotactic factors such as monocyte chemoattractant protein-1 (MCP-1) by tubular cells and ICAM-1 in renal microvascular endothelial cells in rats [35–38]. Fructose also increased proteinuria with an acceleration of renal dysfunction and glomerulosclerosis in the remnant kidney model, suggesting that fructose initiated and accelerated the kidney injury. Importantly, these changes in the kidneys were not observed in rats fed an equivalent glucose-based diet [38]. The toxic effect of fructose in renal tubular cells is likely driven by uptake passage of fructose into the glomerular filtrate, uptake of urinary fructose via the fructose transporter, Glut5, into the proximal tubule, and metabolism by fructokinase in the cytosol [35]. Indeed, the metabolism of fructose in proximal tubular cells by fructokinase results in intracellular ATP depletion, oxidative stress, uric acid generation, and the production of chemotactic factors such as MCP-1 [36]. Finally, hemodynamic studies in rats documented that fructose intake alters renal autoregulation by inducing preglomerular arteriolar arteriosclerosis, resulting in glomerular hypertension and a reduction in renal blood flow [39].

## Clinical studies

Several clinical studies indicated that fructose intake is positively associated with an elevation of serum creatinine, an induction of urinary albuminuria, and a decline in estimated glomerular filtration rate (eGFR) [40–42]. Specifically, the NHANES (1999–2004) found that intake of two or more sugar-containing beverages was associated with an increased risk of having albuminuria [41]. In prospective analysis using the Nurses' Health Study Cohort, a consumption of  $\geq 2$  servings per day of artificially sweetened (diet) soda was independently associated with eGFR decline  $\geq 30\%$  [odds ratio (OR) 2.02, 95% confidence interval (CI) 1.36–3.01] and  $\geq 3$  mL/min/1.73 m<sup>2</sup>/year (OR 2.20, 95% CI 1.36–3.55) [42]. More recently, a study evaluating the association between all types of beverages and CKD risk in community-based cohort of black Americans also confirmed that both soda and sweetened fruit

drinks are identified as a risk factor for incident CKD [43]. However, there remains some controversy. For example, one study reported that consumption of sugar-sweetened beverages was not associated with disease progression in CKD patients on the basis of either eGFR or albuminuria [44]. However, the negative data may relate to the level of exposure, as studies evaluating the effects of consumption of one soft drink or less usually do not see an association of soft drinks with kidney disease while those drinking two or more do find an association [42].

## Fructose and uric acid

### Fructose metabolism results in uric acid synthesis as a by-product

One of the mechanisms that potentiates the deleterious effect of fructose is uric acid. As mentioned previously, uric acid is generated in the process of fructose metabolism. Not only an acute rise of serum uric acid after fructose intake, but a chronic high-fructose ingestion also led to an elevation of uric acid levels. The intake of a large amount of fructose in men for 12 days markedly raised both serum and urinary uric acid levels [45].

Importantly, lowering uric acid by a xanthine oxidase inhibitor ameliorates most phenotypes of metabolic syndrome and kidney disease induced by fructose [26,46]. It also seems a case in humans as several pilot clinical trials have demonstrated that the treatment for hyperuricemia improves blood pressure and insulin sensitivity [22,37,46,47]. While uric acid was often considered an inert substance [32], or even a beneficial factor due to its antioxidative effects [48], accumulating evidence suggests that uric acid directly or indirectly acts on different cell types to be proliferative, proinflammatory, vasoconstrictive, and prooxidative [49–51].

### Role of fructose-induced uric acid production in the development of metabolic syndrome, hypertension, and kidney disease

As discussed earlier, fructose metabolism by fructokinase is associated with adenine nucleotide turnover, with the stepwise degradation of AMP to its final end product, uric acid (Fig. 43.1). Indeed, the ingestion of fructose results in an acute increase in intracellular uric acid in the liver with release into the circulation. This has led to the development of a fructose tolerance test, which measures the change in serum uric acid following ingestion of a set amount of fructose [24]. While the original concern with fructose-induced hyperuricemia related to its potential risk to cause gout, there has been increasing evidence that the

adenine nucleotide degradation pathway, and especially the uric acid generated, may be mediating many of the metabolic effects of fructose.

For example, several studies have reported that xanthine oxidase inhibitors, such as allopurinol and febuxostat, can block many of the features of fructose-induced metabolic syndrome, including the hypertriglyceridemia, insulin resistance, hypertension, and fatty liver [20,26,52,53]. Similarly, uricosurics also protect against fructose-induced metabolic syndrome in the rat [26]. One study in rats also showed that sucrose-induced type 2 diabetes was also associated with a loss of islet cell function that likely involved uric acid, as the islets were shown to express urate transporters and uric acid induced oxidative stress in pancreatic islet cells in culture [54].

High-fructose intake in humans is also associated with elevated serum uric acid, especially in the postprandial period [55]. In turn, hyperuricemia is also associated with hypertension, metabolic syndrome, and kidney disease [56]. While there continues to be debate on the role of uric acid in these conditions, there is increasing evidence that uric acid likely has a role in hypertension, insulin resistance, and CKD [56,57].

The potential mechanisms by which uric acid may be involved in driving metabolic disease have been intensively studied. Although it is an antioxidant in the extracellular environment, one of its earliest effects is to induce oxidative stress that involves both stimulation of the NADPH oxidase system and mitochondrial metabolism [21]. There is also a stimulation of NF $\kappa$ B in various cell types, including vascular smooth muscle cells and tubular cells, activating inflammatory pathways with the release of chemokines and vasoactive factors [51,58]. These include the stimulation of the intracellular renin–angiotensin system, endothelin, and thromboxane [59–61]. Renal tubular cells also develop oxidative stress and can undergo dedifferentiation into mesenchymal cells [58,62].

### **Renal handling of fructose in subjects with chronic kidney disease and dialysis**

Fructose is absorbed in the gut primarily through the Glut5 transporter, and then is metabolized in the intestine, followed by the liver and then other sites. In subjects who have not been exposed to a lot of sugar, the expression the Glut5 transporter is low, and absorption of fructose is often poor, such that malabsorption is common. However, in subjects exposed to soft drinks or fructose-rich foods, the expression of Glut5 can be rapidly induced, resulting in increased absorption that can translate into stronger metabolic

effects. Likewise, fructokinase is also induced by fructose, as well as its product, uric acid [20,54]. Thus a study in children reported that lean subjects showed significant fructose malabsorption to an oral fructose load, but it was less in those who were obese and minimal in subjects who had obesity and biopsy-proven NAFLD [63].

Subjects with CKD often have hyperuricemia associated with the reduction in kidney function [64–66] and might be expected to have upregulated Glut5 and fructokinase expression with more pronounced increases in serum fructose in response to an oral fructose challenge. However, while baseline serum uric acid levels are higher, the relative increase in uric acid was less in subjects with CKD [67]. In contrast, subjects on hemodialysis showed delayed absorption of fructose but with a greater rise in serum uric acid [68]. The reason for these findings is not fully understood. It is known that uric acid can inhibit xanthine oxidase in a negative feedback loop at least partially, so that the presence of high uric acid may have some effects to block its further production. It is also possible that subjects with CKD have a low ATP state that may result in less substrate availability for urate generation.

### **Guideline for fructose intake in chronic kidney disease patient**

CKD patients are generally restricted in the intake of protein, phosphate, and salt, but often not for carbohydrate and sugars. Therefore CKD patients may be exposed to higher fructose intake and become vulnerable to metabolic effect of high fructose. Patients with CKD are at high risk for both heart disease and progression of their kidney disease. Many are also diabetic. However, once on dialysis, some subjects can become cachectic with a cachexia-like syndrome. Indeed, as debility increases, conditions such as obesity and hypertension may be associated with better survival, and a reversed pattern has also been observed for hyperuricemia. This has led to general questions on the ideal diet for the patient with kidney disease.

Our recommendation is that foods containing refined sugar and HFCS should be recognized as foods that may increase adipose mass, induce insulin resistance, and stimulate fatty liver. This is especially true for sugar provided in a liquid form, such as soft drinks, power drinks, sugary teas, and fruit punches. These drinks often contain a lot of fructose and the rapid intake can result in high-fructose concentrations in the liver that can increase its metabolic effects [4]. Fruit juices can also contain high concentrations of fructose and should be avoided [4]. In contrast,

**FIGURE 43.2** Effect of fructose in the development of hypertension, fatty liver, diabetes, and kidney disease. *Glut2/5*, Glucose transporter 2/5; MCP-1, monocyte chemoattractant protein-1; TG, Triglyceride. [74]. Source: From Johnson RJ, Sanchez-Lozada LG, Nakagawa T. The effect of fructose on renal biology and disease. *J Am Soc Nephrol* 2010;21(12):2036–9.

natural fruits contain less fructose and also have other components that either delay absorption (fiber) or block the metabolic effects of fructose (epicatechin, vitamin C) [69]. Indeed, we recommend natural fruit as the food of choice when an individual desires something sweet (taking into the potassium content of the fruit). Many fruits contain potassium, so this needs to be factored in the discussions when recommendations for fruit are given. In terms of recommendations related to refined sugar, we would follow the American Heart Association recommendation of limiting 25-g sugar (six teaspoons) for women and 37.5 g (nine teaspoons) for men as the daily limit [70].

In addition, special concerns include the following. First, for the subject with severe hypertension, reducing both sugar and salt is key. Both sugar and salt stimulate thirst and, hence, might lead to greater weight gain between dialysis runs. Fructose ingestion also leads to an immediate rise in blood pressure [71]. Further, there is evidence that sugar may drive some of the effects of salt [72]. Second, in the patient with comorbid liver disease, sugar is now recognized as the major risk factor for nonalcoholic fatty liver, and restriction of sugar is key to help prevent worsening of the liver disease [73]. Third, liquid sugar should be viewed as a risk factor for renal progression, and restriction of soft drinks is important in the subject with CKD, especially if it is progressing [74].

Of importance, however, is the subject with cachexia. We recommend liberalizing the diet fully for these individuals, as malnutrition may be a greater risk than obesity. Clinical judgment is important, but in the highly catabolic

or wasted individual, the use of sugar to stimulate appetite and to increase weight mass may be beneficial.

## Conclusion

There is increasing evidence that dietary exposure to fructose can possibly have substantial metabolic effects predisposing individuals to diabetes, hypertension, fatty liver, and kidney disease (Fig. 43.2), which is potentially mediated by an elevation of uric acid. Given the consideration of cardiovascular and metabolic comorbidities in CKD patients, fructose intake needs to be reduced unless the patients demonstrate evidence of malnutrition. More clinical studies are warranted to determine the effect of dietary fructose restriction on renal progression in CKD patients.

## Introduction

Protein-energy wasting (PEW) is used to describe the depletion of body protein mass, decreased fat mass, and/or energy fuel supplies in patients with chronic kidney disease (CKD) [1]. PEW is prevalent in patients with advanced CKD (Stages G3B–G5) [estimated glomerular filtration rate (eGFR) < 45 mL/min/1.73 m<sup>2</sup>], with manifestations developing along with a reduction in the GFR and becoming more common as patients reach end-stage kidney disease (ESKD) requiring maintenance dialysis [2]. Depending on the method used to assess PEW, it is present in 20%–54% of people with advanced CKD [3–6] and up to 60% in maintenance dialysis patients [6–11]. Most patients exhibit mild-to-moderate degrees of PEW and 6%–8% have severe PEW [12,13].

The causes of PEW in advanced CKD are complex and multifactorial and include a buildup of uremic toxins that contributes to anorexia and reduced protein and energy intake, inflammation, and superimposed catabolism [14]. Diminishing appetite in Stage G4 with marked decreases in Stage G5 result in a spontaneous reduction in dietary energy and protein intake that is often accompanied by worsening nutritional status [15]. This is one of the most significant clinical indicators of progressive kidney disease. Moreover, the dialysis treatment itself is a catabolic process that contributes to PEW. The dialysis membrane, dialysis access, and nutrients lost during the dialysis procedure such as amino acids and protein reduce nutrient availability. These nutrient losses coupled with inadequate

protein and energy intake contribute to the breakdown of muscle proteins and increases the risk of PEW. Metabolic derangements such as hyperparathyroidism, metabolic acidosis, endocrine disturbances, and decreased insulin also contribute to PEW. Lastly, increased production of inflammatory cytokines such as tumor necrosis factor- $\alpha$  and interleukin-6 also cause PEW (see Chapter 13: Causes and treatment of protein-energy wasting in kidney disease).

PEW is manifested by low levels of serum albumin or prealbumin, sarcopenia, weight loss, vascular calcification, and increased levels of C-reactive protein, and it is closely associated with increased risk of morbidity and mortality and impaired quality of life [2]. PEW is both preventable and treatable with an early diagnosis and nutrition interventions [i.e., nutrition counseling, oral nutritional supplements (ONS), and enteral nutrition (EN, tube feeding)].

The nutrition goals for treatment and management of CKD are dependent on the patient's nutritional status and metabolic condition, and the type and stage of kidney disease. Because of the high prevalence of PEW in patients with CKD, and its detrimental effects on quality of life, morbidity, and mortality, several nutrition guidelines and consensus statements have been developed to address prevention and treatment strategies for managing PEW [2,16–20]. In general, these documents provide recommendations for assessing, monitoring, and evaluating treatment for PEW and requirements for macro- and micronutrients and electrolytes. More recently, the 2020 Kidney Disease Outcomes Quality Initiative (KDOQI) Clinical Practice Guideline for Nutrition in CKD provided

recommendations for medical nutrition therapy (MNT), which includes, but is not limited to, nutrition counseling and nutrition support [20].

ONS and EN (tube feeding) are the routes of choice for nutrition support in patients with, or at risk for, PEW [16,20,21]. However, the guidelines for the use of ONS and EN in CKD were developed based on expert opinion because: (1) large randomized controlled trials (RCTs) that assessed the effects of nutrition support on nutritional status and morbidity and mortality in patients with CKD are lacking and (2) there are a limited number of oral or enteral formulas that have been developed specifically to meet the metabolic needs of patients with CKD. Therefore their efficacies with regards to both nutritional benefits and prognostic effects in the CKD population have not been thoroughly examined. This chapter will address the oral and EN supplements used to prevent and treat established PEW in patients with advanced CKD [Stages G3B-G5 (nondialysis)] and ESKD [maintenance hemodialysis (MHD) and chronic peritoneal dialysis (CPD)]. In addition, the use of these ONS and EN in patients with nephrotic syndrome will be discussed briefly.

### **Advanced CKD [Stages G3B-G5 (nondialysis)]**

#### **Treatment of patients with ONS and EN**

The nutritional challenge in treating patients with advanced CKD is to simultaneously ensure, on the one hand, the preservation of kidney function using low-protein diets and controlling blood pressure and blood glucose levels and, on the other hand, the prevention or treatment of established PEW. Part of the challenge is that these patients require close monitoring of protein and energy intakes and nutritional status before dialysis begins to detect and prevent PEW. This should be a priority since PEW in patients commencing dialysis is associated with higher morbidity and mortality rates during the first year of treatment [22]. Unfortunately, the majority of adults in the United States with CKD are unaware of their diagnosis; they never receive MNT and most remain poorly informed about how diet influences kidney disease management and progression. Most patients are not referred to or do not seek nutrition guidance from a nephrology registered dietitian nutritionist (RDN) (or international equivalent) for MNT until they develop kidney failure and start dialysis [23]. According to data from the US Renal Data System, less than 10% of CKD patients were referred to an RDN before the initiation of dialysis [24]. MNT has been demonstrated to improve clinical outcomes in CKD patients [25–27]. Until recently, clinical practice

guidelines in kidney disease did not emphasize the role of RDNs in the treatment and management of patients with nondialysis-dependent CKD. However, the 2020 KDOQI Clinical Practice Guideline for Nutrition in CKD, which was developed in collaboration with the Academy of Nutrition and Dietetics, includes statements regarding MNT in patients with all stages of CKD, including posttransplantation [20].

A stepwise approach to nutrition intervention should be used to treat and manage patients with advanced CKD (see Fig. 44.1). Nutrition intervention begins with periodic nutrition assessments and nutrition counseling by an RDN in the form of MNT. The RDN should monitor nutritional status every 1–3 months and more frequently if there is inadequate nutrient intake, established PEW, or the presence of an illness that may worsen nutritional status, as these are predictive of increased morbidity and mortality risk [28]. Nutrition counseling, which is aimed at implementing behavioral change strategies that empower patients to adhere to the renal diet, is an integral component in the management of these patients. They require specialized nutrition care and ongoing monitoring by an experienced nephrology RDN to prevent nutritional inadequacies and subsequent PEW. When there is no improvement in markers of nutritional status (e.g., sufficient energy and protein intakes to meet nutritional requirements) or deteriorating nutritional status that places the patient at risk of PEW, more intensive strategies such as a 3-month trial of ONS is recommended [20]. The nutrition supplement should be specific for advanced CKD patients, that is, it should be energy dense with reduced protein and electrolytes (i.e., potassium, phosphate, and sodium) to meet the patient's high energy needs and conform to the low protein and electrolyte requirements. In patients with chronically inadequate intake and whose protein and energy needs cannot be met by nutrition counseling and ONS, a trial of EN (tube feeding) is suggested [20].

Although ONS and EN may be useful in advanced CKD patients with PEW, there have been very few studies that examined the effectiveness of these interventions on clinical outcomes these patients. Thus far, only one RCT [29] showed that a nonprotein calorie supplement was effective in preserving kidney function and nutritional status in advanced CKD patients on a low-protein diet. As a result, the evidence-based statements in the 2020 KDOQI guideline about ONS and EN in patients with CKD were developed based on expert opinion [20]. Finally, in patients with no obvious severe, superimposed catabolic illness, the presence of PEW in spite of aggressive nutritional management (e.g., ONS and EN) may be an indication to initiate dialysis treatment [30].

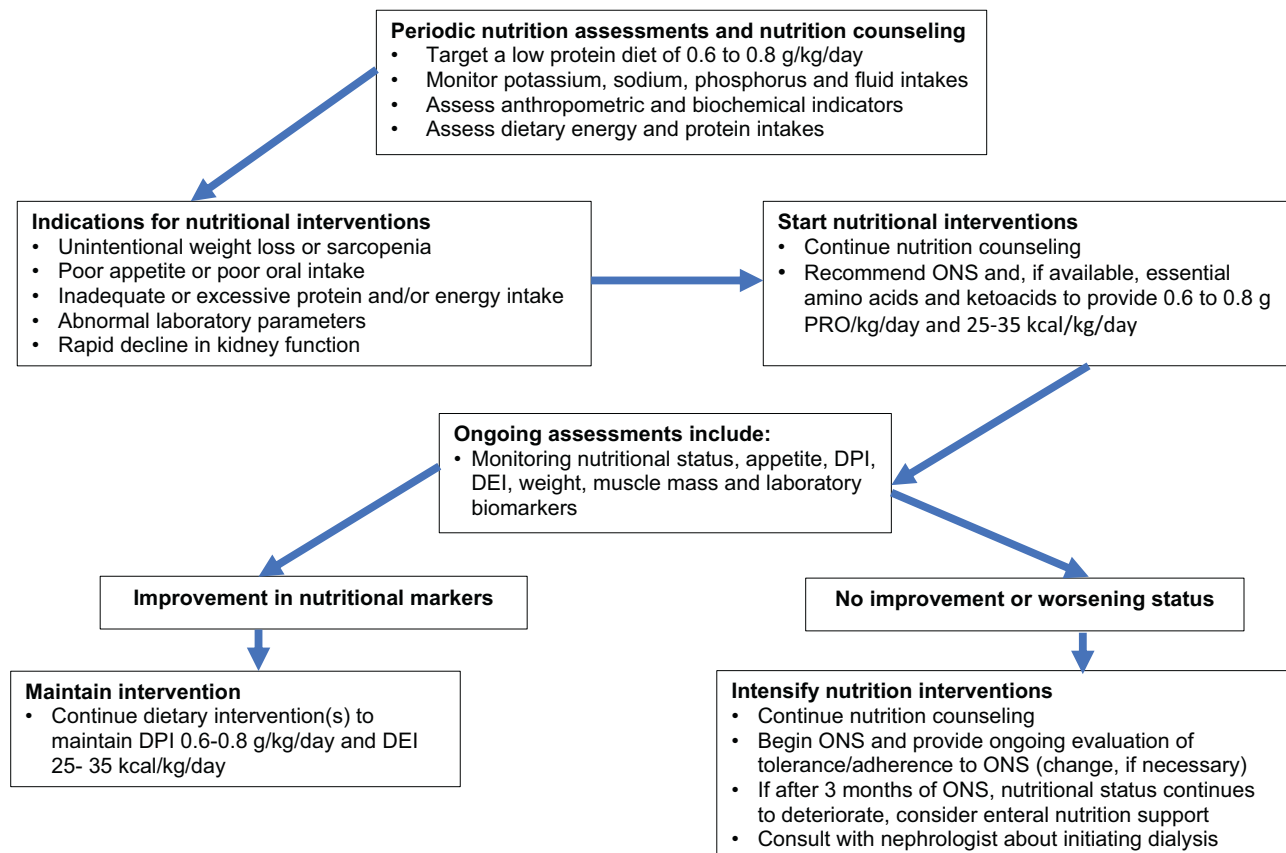

FIGURE 44.1 Suggested algorithm for assessment of treatment of protein-energy wasting in patients with advanced CKD (stages 3–5). CKD, Chronic kidney disease; DEI, dietary energy intake; DPI, dietary protein intake; EAA, essential amino acids; ONS, oral nutritional supplements; PRO, protein. Source: Modified from Kovesdy CP, Kopple JD, Kalantar-Zadeh K. Management of protein-energy wasting in non-dialysis-dependent chronic kidney disease: reconciling low protein intake with nutritional therapy. *Am J Clin Nutr* 2013;97:1163–77. Permission pending.

## Indications for ONS and EN

Essential amino acid and ketoacid preparations that are prescribed and administered with very low-protein diets for patients with advanced CKD are not addressed in this chapter (see [Chapter 16](#): Dietary interventions to slow the progression of chronic kidney disease and improve metabolic control of uremia). Furthermore, recommendations for macro- and micronutrient intakes are discussed in detail in [Chapter 29](#), Nutritional approaches and plant-dominant diets for conservative and preservative management of chronic kidney disease. An energy intake of at least 25–35 kcal/kg body weight (BW)/day and 0.6–0.8 g protein (PRO)/kg BW/day is recommended in patients with advanced CKD [20]. When spontaneous dietary intake cannot meet these requirements, ONS should be prescribed two to three times daily to ensure that the recommended intakes are met to prevent PEW or to treat the existing condition. Patients should be advised to take ONS preferably 1–2 hours after meals rather than as a meal replacement to maximize benefit [2].

Standard products for oral and EN support contain a mixture of whole protein and/or amino acids, glucose polymers, fat components and added vitamins, minerals, electrolytes, and trace elements. These products are not routinely recommended for patients with advanced CKD because they are usually high in protein and provide substantial amounts of electrolytes (i.e., phosphorus, sodium, and potassium) that may need to be limited in the diet. However, these products may be used by some patients because of cost and lack of availability of the specialized formulas on the global market. As such, regular monitoring and evaluation of serum chemistries are important, and implementations of the necessary changes to the ONS prescription are crucial measures to ensure the overall safety and effectiveness of oral nutrition supplementation.

Polymeric formulas developed specifically for patients with kidney disease are preferred since they contain modified amounts of protein and greater energy density (up to 2.0 kcal/mL), and they are electrolyte-restricted [31]. Some of the ONS are also nutrient-specific

(i.e., composed solely of protein or nonprotein calories). A number of these products are well tolerated and have been shown to increase protein and energy intakes [32]. However, their effects on nutritional parameters, morbidity and survival, have not been examined fully in clinical trials. ONS are also available in different preparations (e.g., milkshake, juice, pudding, energy bar, or powder, which may be added to foods or beverages to increase protein and/or energy intake); the choice of preparation is dependent on the patient's preference, tolerance, and acceptability. Using a variety of preparations may decrease monotony, which can lead to flavor and taste fatigue and eventually nonadherence to the ONS [33]. The RDN should monitor and evaluate the patient regularly throughout the supplementation period, since adjustments to the ONS prescription may be necessary to improve adherence and to optimize effectiveness.

Table 44.1 provides a list of commercial supplements available in the United States and abroad for advanced CKD. Nepro LP (Abbott Nutrition Abbott Laboratories, Columbus, OH) (LP stands for Low Protein) and Suplena with Carb Steady (Abbott Nutrition Abbott Laboratories, Columbus, OH) are two examples of ONS for advanced CKD. These and other commercial products are designed for both oral nutrition and enteral feedings, and as supplemental or sole-source nutrition.

EN feedings are also indicated in advanced CKD patients who are hospitalized or institutionalized, and who are unable to consume adequate amounts of nutrients. Moreover, patients who cannot consume sufficient ONS to meet their needs, who have acute stress conditions, who have certain neurological diseases, dementia, pharyngeal, or esophageal obstruction, or who are unconscious, may require EN feedings [16,34]. EN is

first administered through a nasogastric tube. When EN is expected to last more than 1 month, a perendoscopic or radiologic gastrostomy should be considered.

### Chronic dialysis patients (Stage G5)

A detailed discussion of nutrition management of MHD and CPD is found in Chapter 31, Nutritional management of maintenance hemodialysis patients, and Chapter 32, Nutritional management of chronic peritoneal dialysis patients, respectively. Most of the clinical research that has addressed the pathophysiology, prevalence, and treatment of PEW in CKD has been performed in patients receiving MHD or CPD [16,21]. In these patients the reported incidence and prevalence of PEW varies from 25% to 70%, depending on the nutritional parameters that were assessed [6–11]. An increased mortality risk associated with PEW in dialysis patients has been described since the early 1980s [35–37]. Since then several RCTs and non-RCTs have examined the effects of ONS on improving nutritional status and clinical outcomes in patients receiving MHD [38–51] and CPD [47,52,53], although the studies in this latter group are limited. (See Table 44.2 for a list of RCTs and non-RCTs that examined the effects of ONS in patients undergoing MHD and CPD.)

Recommendations for dietary intake of macro- and micronutrients and electrolytes in patients receiving MHD and CPD are discussed in Chapter 31, Nutritional management of maintenance hemodialysis patients, and Chapter 32, Nutritional management of chronic peritoneal dialysis patients, respectively. The recommended intakes of dietary energy and protein for these patients are 25–35 kcal/kg BW/day and 1.2 g/kg BW/day,

respectively [20]. Studies have shown that most MHD patients consume less energy and protein than recommended. In the HEMO Study, patients consumed an average of 23 kcal/kg/day and 0.93 g PRO/kg/day, which is less than recommended [54]. Several studies have evaluated dietary energy and protein intakes among patients receiving CPD and estimated a daily intake of 22–25 kcal/kg (from diet alone) and 0.85–1.1 g PRO/kg [55–59].

Peritoneal dialysis (PD) is associated with glucose absorption from the dialysate. Traditional PD solutions are high in glucose and provide about 300–600 kcal/day, depending on the peritoneal transport rate and the dialysis prescription [21,60]. These additional calories compensate for the potentially low energy intake in patients receiving CPD [61], but it may contribute to weight gain [62,63] and the metabolic syndrome [60] in some patients. Total energy intake is higher in patients receiving CPD than MHD because it includes calories absorbed from the dialysate; energy intake may be close to 30 kcal/kg/day in the former group. On the other hand, protein is especially important among patients receiving CPD because of the protein wasting that occurs during dialysis. It is estimated that 5–15 g of protein and 3–4 g of amino acids are lost per day in the dialysate effluent; these losses are substantially increased during episodes of peritonitis [21].

### Treatment of patients with ONS and EN

Since MHD patients with PEW commonly ingest fewer calories than recommended, nutrition

supplements prescribed to these patients should provide about 10 kcal/kg/day to attain the recommended intake. Providing nutrition support to dialysis patients in a timely manner, in the form of either ONS or EN, will ensure that they receive adequate protein and energy to meet their needs. ONS given two to three times a day can provide additional energy of 7–10 kcal/kg/day and protein of 0.3–0.4 g PRO/kg/day, depending on the formula used. These additional calories and protein make it possible to attain the recommended levels of protein and energy intakes that cannot be obtained spontaneously through a normal diet.

Few ONS specifically developed for dialysis patients are commercially available on the global market [1]. Table 44.1 provides a list of some commercial supplements available for patients receiving maintenance dialysis in the United States and abroad. Nepro HP (Abbott Nutrition Abbott Laboratories, Columbus, OH) (HP stands for High Protein) and Novasource (Nestle Health Science, Bridgewater Township, NJ) are two examples of ONS for chronic dialysis patients. These and other commercial products are designed for both oral and enteral feedings, and as supplemental or sole-source nutrition. Standard oral nutrition formulas are commonly used because specialized products may not be widely available in every country. If these standard products must be used, choose ones that are protein and energy dense, and limited in potassium, phosphorus, and sodium content. Moreover, they should not be consumed on a long-term basis.

The following practical rules may improve the efficiency of ONS [16,64]: (1) ONS should be given

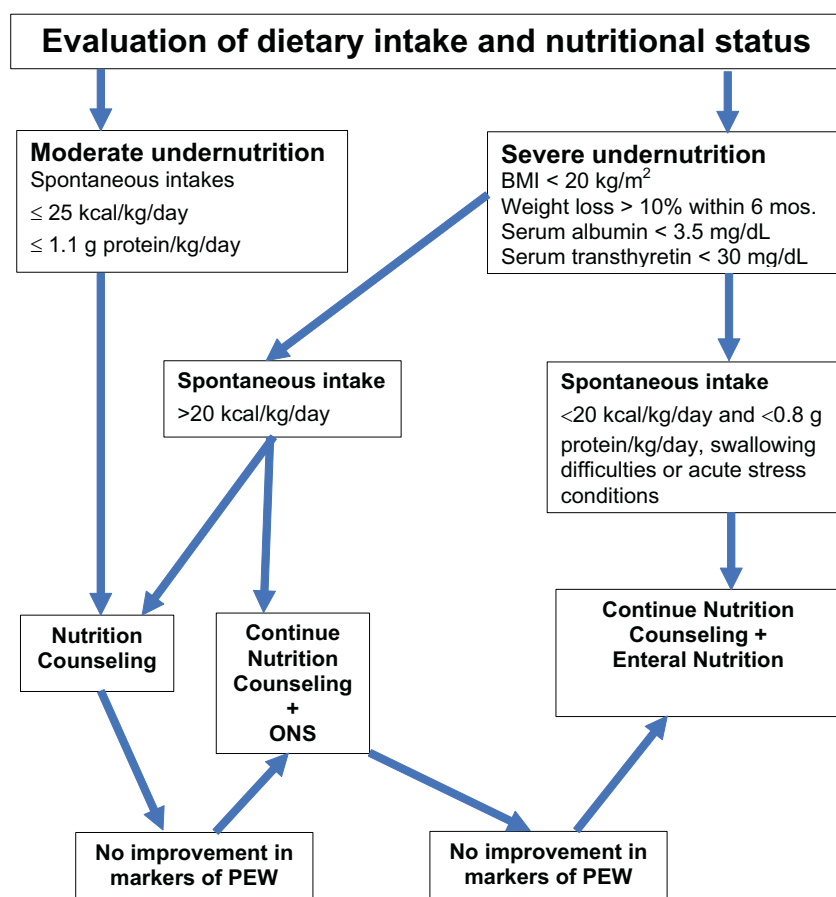

FIGURE 44.2 Algorithm for the management of PEW in maintenance dialysis patients. BMI, body mass index; ONS, oral nutritional supplements; PEW, protein-energy wasting. Source: Modified from Cano NJ, Aparicio M, Brunori G, Carrero JJ, Cianciaruso B, Fiaccadori I, et al. ESPEN Guidelines on Parenteral Nutrition: adult renal failure. *Clin Nutr* 2009;28:401–14. Permission pending.

separately from regular meals, usually 1–2 hours after the main meals to perform true nutrition supplementation and not simply a nutrition substitution; (2) ONS can be given during the hemodialysis treatment to prevent dialysis procedure-associated alterations of protein metabolism; and (3) a late evening meal or ONS may be useful to reduce the length of nocturnal nutrient deprivation and the associated increased consumption of endogenous protein and fat mass.

Table 44.2 summarizes the results of RCTs and non-RCTs of ONS administration versus no supplementation, nutrition counseling only, or treatment with intradialytic parenteral nutrition for MHD and CPD patients who had some evidence of PEW. Although these clinical trials were heterogeneous with regard to study design, the measured nutritional outcomes [e.g., serum albumin, subjective global assessment (SGA), dietary energy and protein intakes, body weight] improved in the 10 RCTs [38–41,44–47,50,51] and 3 non-RCTs [43,48,49] conducted in MHD patients,

as well as the 3 RCTs performed in CPD patients [47,52,53].

EN (tube feeding) is indicated in chronic dialysis patients when PEW is associated with spontaneous protein and energy intakes less than 0.8 g PRO/kg/day and 20 kcal/kg/day, respectively, and when dietary intake does not improve sufficiently with nutrition counseling or ONS (see Fig. 44.2). In these patients, EN helps to maintain normal structure and functioning of the digestive tract [16]. A few cohort studies of EN in MHD patients have shown that nutritional parameters improved [65,66]; however, clinical trials of EN in adult CPD patients have not been published.

EN is most often used when patients are not able to tolerate oral feedings and ONS are not able to satisfy nutritional requirements in conditions such as severe anorexia, swallowing difficulties secondary to neurologic or head and neck diseases, the perioperative period, and superimposed systemic illnesses. In these situations, EN should provide all of the required macro- and micronutrients. Protein and hypercaloric nutritive

mixtures are preferably used. When prescribing EN for patients with ESKD, the water, sodium, potassium, and phosphorus content of the preparation should be taken into account. If the duration of EN feeding is expected to exceed 1-month, surgical placement of a percutaneous endoscopic gastrostomy (PEG) or percutaneous endoscopic jejunostomy (PEJ) should be considered. Due to an increased risk of peritonitis, PEG or PEJ is contraindicated in adult CPD patients.

An algorithm for nutrition support of chronic dialysis patients with PEW has been proposed by the European Society of Clinical Nutrition and Metabolism (see Fig. 44.2) [67].

1. In patients presenting with mild nutritional depletion, as defined by insufficient spontaneous intakes, dietary counseling, and if necessary ONS, should be prescribed.
2. In patients exhibiting PEW and spontaneous dietary energy intake is  $>20$  kcal/kg BW/day, dietary counseling and ONS should be prescribed. EN may be recommended when ONS cannot meet nutritional requirements.
3. In patients with PEW and spontaneous dietary energy intake is  $<20$  kcal/kg BW/day, or in stress conditions, daily nutrition support is necessary. EN should be preferred to parenteral nutrition (see Chapter 45: Intradialytic parenteral nutrition, intraperitoneal nutrition, and nutritional hemodialysis).

Some patients receiving MHD do not respond to nutrition support. In these patients, therapeutic approaches, including treatments aiming to improve appetite, to decrease protein breakdown, and/or to promote protein synthesis, have been proposed in the EBPG [18]:

- Exercise training, which is demonstrated to improve protein synthesis and to increase muscle performance and possibly muscle mass, should be proposed after cardiovascular assessment establishes its safety.
- Similarly, in the case of severe PEW resistant to optimal nutritional intervention, a 3- to 6-month course of androgenic compounds may be given to MHD patients in the absence of contraindications. Such patients should be monitored at regular intervals for side effects (e.g., hirsutism, voice change, priapism, alteration in plasma lipids, liver tests, and blood tests for prostate cancer).
- Consider a 6- to 12-month trial of daily dialysis (either short daily or long nocturnal) as therapy for MHD patients who are frail, those who exhibit a failure to thrive and/or have PEW that is resistant to nutrition support and other therapies.

To improve protein nutrition, therapies such as the administration of essential or branched-chain amino acid supplements [39,45] and the modulation of inflammation by pentoxifylline, for example, have been proposed [68–71]. These data suggest that an integrated multimodal management that combines nutrition support, exercise and, in selected patients, anabolic and anticatabolic agents may be the optimal treatment for PEW in chronic dialysis patients [42].

### Provision of ONS during the hemodialysis treatment

Over the last few years, an increasing number of dialysis facilities have encouraged and even provided patients with ONS to be consumed during the hemodialysis treatment. The International Society of Renal Nutrition and Metabolism has issued a statement regarding eating during hemodialysis, which states that “nutrition during dialysis should be considered as a part of the standard-of-care practice for hemodynamically stable patients who have no contraindications and no history of intolerance to consuming food during treatment” [72]. This practice is routine in many nations such as Germany, France, and the United Kingdom; it remains controversial in the United States and in some other countries. Several studies have indicated that provision of an ONS with a high protein and energy content during hemodialysis is associated with a modest improvement in serum albumin concentration and a slight increment in body mass index [73–75], SGA, and malnutrition–inflammation score [40,76]. In addition to improving these markers of nutritional status, providing ONS during treatment may also improve patient adherence and satisfaction [77]. More clinical trials are needed to establish whether this practice reduces morbidity and mortality.

Since many patients bring their own food and eat during the hemodialysis treatment, dialysis clinics could provide a specifically formulated ONS for dialysis patients at risk of or with established PEW. This would ensure that patients are receiving about 400 kcal and 20 g protein during each treatment. Dietitians could also use this time as an opportunity to provide nutrition education and to reinforce the importance of consuming adequate dietary energy and protein intakes to prevent and/or treat established PEW.

The other side of this debate is that providing ONS and meals during the dialysis treatment contributes to postprandial hypotension, reduction in treatment efficiency, gastrointestinal symptoms, aspiration, increased staff burden, and infection control and hygiene issues [72,78]. Controlled trials are needed to examine the

safety and efficacy of providing meals and ONS during the hemodialysis treatment and its effects on outcomes.

## Nephrotic syndrome

### Nutritional and metabolic particularities of nephrotic syndrome

Patients with nephrotic syndrome exhibit specific metabolic disorders that should be taken into account when designing their nutritional management plan (see [Chapter 28: Nutritional and nonnutritional management of the nephrotic syndrome](#)). Insulin resistance is frequent and can be worsened by corticosteroid and other immunosuppressive treatments [79]. Metabolic studies showed similar rates of whole-body protein metabolism in patients with nephrotic syndrome as compared to controls. However, tissue-specific studies show that liver protein synthesis is increased whereas muscle protein synthesis is reduced [80]. Patients with nephrotic syndrome also exhibit abnormalities in lipid metabolism that mainly consist of increased plasma concentrations of low-density lipoprotein (LDL) cholesterol, lipoprotein (a), and very LDL [81]. These patients are also characterized by sodium retention [82], hypocalcemia, and low serum vitamin D levels due to the urinary losses of vitamin D and vitamin D transport protein [83].

### Nutrition requirements, ONS, and EN

A personalized nutrition evaluation is needed for patients with nephrotic syndrome. High-protein diets, which had been proposed to prevent PEW, were shown to increase proteinuria and reduce kidney function [80,84]. On the other hand, modestly restricted low-protein diets have been shown to decrease proteinuria, to increase serum albumin levels, and to maintain nitrogen balance [84]. It should be emphasized that such regimens have only been investigated in clinically stable patients and during short-term studies (e.g., 1 month). Therefore the long-term effects of modestly reduced protein diets on nutritional status, as well as their tolerance by clinically unstable patients with nephrotic syndrome, are unknown [80,83,84].

The risk of PEW during long-term treatment with low-protein diets has not been evaluated in nephrotic patients. A protein supply of 1 g/kg BW/day or 0.8 g PRO/kg BW/day plus the compensation for urinary protein losses appears to be a good approach. Monitoring nephrotic patients by urinary urea excretion and urinary protein losses makes it possible to assess adherence to the prescribed regimen [84]. Other dietary recommendations include an energy intake of 30–35 kcal/kg BW/day, the exclusion of

sugars that have rapid gastrointestinal absorption, and a limited fat intake [83]. Therapies that reduce proteinuria contribute to an improved serum lipid profile [81]. Regular exercise, vitamin D, and calcium supplementation have been proposed to prevent osteoporosis [83]. Because of water and sodium retention, sodium chloride intake should not exceed 4 g/day in adults [82].

The effects of ONS and EN have not been evaluated for the treatment of nephrotic patients with PEW. However, since these patients may need aggressive nutrition support, ONS as well as EN should be prescribed similar to patients with advanced CKD (i.e., with high-energy low-protein products).

## Conclusion

The spectrum of kidney diseases includes very different nutritional and metabolic conditions that require specific nutrition management. Patients with CKD generally share a common phenotype with patients who have other chronic diseases that is responsible for similar losses of muscle mass, visceral proteins, and fat stores. The causes for PEW in these individuals include anorexia, reduced spontaneous nutrient intake, physical inactivity, anemia, inflammation, and insulin resistance. Although data concerning the treatment of PEW in patients with advanced CKD patients are limited, ONS or EN can be indicated when PEW or superimposed acute illnesses occur.

MHD and CPD contribute additional causes for PEW. The independent adverse effect of PEW on the survival of chronic dialysis patients has been known for nearly 40 years. In MHD patients, the beneficial effects of ONS on improving protein–energy nutritional status has been demonstrated; more clinical trials are needed to establish their effectiveness in CPD.

## Introduction

Protein-energy wasting (PEW) is a robust risk factor for unpropitious outcomes, including death, in maintenance hemodialysis (MHD) and chronic peritoneal dialysis (CPD) patients. Reduction in body mass index and muscle mass, low serum levels of albumin and transthyretin, inadequate appetite and food intake, and measures indicating inflammation are indicators of PEW. Adequately powered, randomized, double-blind clinical trials that examine whether nutritional support improves clinical outcome in MHD and CPD patients are not available. However, some randomized prospective clinical trials do give valuable insights and indicate that protein–energy status can be improved in MHD patients with PEW. Also, nonrandomized studies, some of which are retrospective, suggest that improving protein–energy status by nutritional intervention improves clinical outcomes in these patients. There is uniform consensus that dietary counseling and oral nutritional supplements should be the initial step in the management of patients with PEW. Low nutrient intakes and disease states, if present, that impair digestion and absorption of nutrients should be identified and treated. If patients are unable to eat adequate amounts of food or food supplements, enteral tube feeding which utilizes the patient's gastrointestinal tract for absorption of nutrients is the next most physiological method to provide nutrients. However, not uncommonly, patients are reluctant to accept an enteral tube as a method of feeding or, due to gastrointestinal disorders, they cannot receive sufficient

nutrition by enteral tube feeding to satisfy their daily requirements. If these conditions persist, or are anticipated to persist, for more than several days, other techniques of nutritional support must be applied.

## Intradialytic parenteral nutrition

Patients for whom enteral nutrition is medically contraindicated or who refuse or respond inadequately to enteral nutrition may be considered for intradialytic parenteral nutrition (IDPN). This treatment offers an alternative method for providing additional nutrients to MHD patients. When prescribed, IDPN is normally administered with each hemodialysis (HD). IDPN is generally infused into the venous line distal to the hemodialyzer at the beginning of the HD session and is usually continued until the end of the HD treatment. It should be emphasized that since most MHD patients undergo HD only three times weekly, IDPN must be viewed as only an adjuvant nutritional therapy, and it cannot be used as the sole source of nutritional support unless patients receive HD daily.

The components of commonly prescribed oral nutritional supplements are listed in Table 45.1, and the nutritional components of a typical IDPN solution are listed in Table 45.2. IDPN solutions are commonly prepared from base solution components. Base solutions for amino acids, carbohydrates, and lipids from which IDPN solutions are prepared can vary in concentrations: up to 10% of essential and nonessential amino acids, 50% or 70% D-glucose, and 10% or 20% lipid emulsions. The lipid infusions can be omitted for short

TABLE 45.1 Content of selected nutrients in some currently available oral nutritional formulations.

	Total carbohydrates (g)	Total protein (g)	Total fat (g)	Total calories (kcal)	kcal/mL
Nepro (240 mL)	39.4	19.1	22.7	425	1.8
Nepro (1000 mL)	166.8	81	96	1800	1.8
Boost glucose control (237 mL)	20	14	12	250	1.06
Boost glucose control (1000 mL)	84	58.2	49.4	1060	1.06
Boost (240 mL)	41	10	4	240	1.0

These nutrients indicate the total amount present in the volume of the solution indicated in the first column. These nutritional supplements also contain other macroelectrolytes, trace elements, and multiple vitamins.

TABLE 45.2 Current recommended intradialytic parenteral nutrition (IDPN) formulations.

Dextrose (infusion rates)	Lipids (infusion rates)	Protein
Moderate-to-high dextrose: carbohydrate 4–6 mg D-glucose/kg/min	Lipids: 4 mg/kg/min or 12–12.5 g/h	Amino acids: 0.6–0.8 g/kg per hemodialysis treatment or per one IDPN bag
Noncarbohydrate controlled 6–8 mg D-glucose/kg/min		
Low dextrose: $\leq 3$ mg/kg/min Low dextrose, no lipids: $\leq 3$ mg/kg/min	Lipids: 4 mg/kg/min or 12–12.5 g/h no lipids	Amino acids: 0.6–0.8 g/kg per hemodialysis treatment or per one IDPN bag. Amino acids: 0.6–0.8 g/kg per hemodialysis treatment or per one IDPN bag

Dextrose and lipids are calculated based on variable infusion rates. Amino acids are calculated based on daily protein requirements or allowances for nonpregnant nonlactating, normal adults or nondialyzed patients with chronic kidney disease, which is 1.2–1.6 g/kg/day. This is not the daily requirement for a nondialyzed CKD patient. These solutions are designed to be infused in 3.5–4 h but some nephrologists may infuse over 3 h in MHD patients who have substantial renal function. Infusion of IDPN over 3 h will probably reduce efficiency of utilization of the nutrients and may increase the risk of complications (e.g., hyperglycemia, post-IDPN hypoglycemia). CKD, Chronic kidney disease; MHD, maintenance hemodialysis.

periods of time (e.g., up to about 2 weeks) or for longer periods of time if patients receive adequate amounts of the essential fatty acids by oral or enteral feeding. Additional components of IDPN solutions commonly include macro-electrolytes and often trace elements and multivitamin formulations. The mineral content of the amino acid, carbohydrate, and lipid solutions must be taken into consideration when prescribing additional minerals to be added to the IDPN solution. The composition of the final IDPN solution can be altered depending on the patient's nutritional needs and metabolic characteristics and the duration of the patient's HD session. Since manufacturing pharmacies often provide IDPN and total parenteral nutrition (TPN) solutions in bulk for many patients, modifying the nutrient composition of IDPN solutions may increase the cost of formulating the solutions.

### Studies of the nutritional and metabolic effects of intradialytic parenteral nutrition

HD is often performed on patients who have been fasting for many hours. Pupim et al. (Fig. 45.1) investigated the acute effects of HD on protein turnover in MHD patients who were in the postabsorptive (fasting)

FIGURE 45.1 Effect of IDPN and oral nutritional supplements on forearm muscle homeostasis. HD, Hemodialysis; IDPN, intradialytic parenteral nutrition; ONS, oral nutritional supplements. Source: Adapted from Pupim LB, Majchrzak KM, Flakoll PJ, Ikizler TA. Intradialytic oral nutrition improves protein homeostasis in chronic hemodialysis patients with deranged nutritional status. *J Am Soc Nephrol* 2006;17(11):3149–57.

state [1]. Eleven clinically stable MHD patients were fasted from at least 10 hours prior to the initiation of the study until 2 hours after the end of the HD. Total-body protein and forearm protein syntheses and

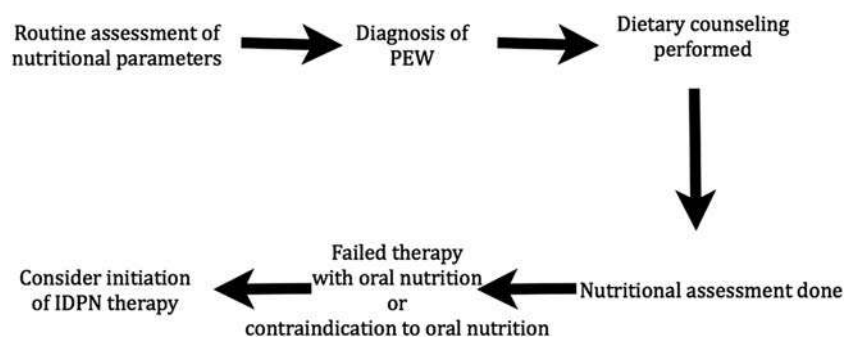

FIGURE 45.2 Decision pathway in managing patients with protein-energy wasting.

degradation were measured immediately before, during, and 2 hours after the end of the HD session (Fig. 45.1). The patients received a constant infusion of L-(1- $^{13}\text{C}$ ) leucine and L-(ring- $^2\text{H}_5$ ) phenylalanine starting 2 hours before HD, which was continued until 2 hours after the HD. The results indicated that degradation of total-body protein and forearm muscle protein increased significantly during dialysis and remained increased at 2 hours after the HD. In comparison to baseline levels, during HD, there was an increase in protein synthesis that was observed in the forearm but not in the total body. Both total-body protein and forearm protein syntheses increased in the postdialysis period as compared with baseline levels. Net protein loss in the forearm increased significantly during dialysis but decreased to baseline levels after dialysis. During HD, total-body net protein balance became significantly more negative (Fig. 45.2).

There is reason to believe that IDPN may improve nutritional status of patients with PEW when it is due at least partly to inadequate protein or energy intake. First, data clearly indicate that the great preponderance of amino acids infused during IDPN are retained in the body and not removed by the hemodialyzer [2]. Also, in clinically stable MHD patients, there is at least a transient increase in protein anabolism during IDPN. In the previous study, Pupim et al. also examined seven clinically stable MHD patients who had no evidence of PEW while they received IDPN during a 4-hour HD [1]. Patients were fasted from 10 hours before a HD until 2 hours afterward, while they received the same amino acid isotope infusions as described earlier. Each IDPN treatment provided solutions containing 300 mL of 15% essential and nonessential amino acids, 150 mL of 50% glucose, and 150 mL of 20% lipids. When these fasting patients received IDPN, total-body protein and forearm protein syntheses were more positive and total-body protein degradation was lower as compared to when they did not receive IDPN (see earlier). During IDPN the patients also had

significantly more positive net forearm protein balance and net total-body protein balance as compared to when they did not receive IDPN. The enhanced anabolic state observed with IDPN had abated at the end the 2-hour postdialysis period. These results indicate that nutritional support in the form of IDPN reduces body and forearm protein loss during HD in fasting, clinically stable MHD patients. Whether these anabolic effects of IDPN during HD would persist if the patients underwent many HD sessions with IDPN was not examined.

This same team of researchers subsequently compared intradialytic oral nutrition (IDON) to IDPN and also to no nutritional support in a separate study of eight clinically stable MHD patients [3]. The IDON provided 57 g of amino acids, 48 g of lipids, and 109 g of carbohydrates for a total of 1090 kcal. This solution was given in three equal feedings at 30, 90, and 150 minutes after the onset of the 4-hour HD. The IDPN solution contained 59 g of amino acids, 26 g of lipids, and 197 g of carbohydrates and 752 kcal. This IDPN solution was given starting 30 minutes after the initiation of HD and continued until the end of the HD session. Compared with when the patients received no nutritional intake, both IDPN and oral nutrition were associated with a significant increase in total-body protein synthesis and decrease in total-body protein degradation. Net total-body protein balance was significantly positive as compared with no nutritional support. At 2 hours after the completion of the HD session, total-body protein synthesis was still elevated only when the patients received IDON. Protein degradation did not differ significantly between the IDON and IDPN groups, but net total-body protein balance was significantly more negative with IDON as compared to IDPN or no nutritional treatment. In the 2 hours after dialysis, forearm protein balance was also significantly more positive when patients were given oral nutrition as compared to IDPN or no nutritional treatment. Although forearm protein degradation was similar among these three different treatments and during the 2-hour postdialysis session,

the net forearm protein balance was significantly more positive with both IDON and IDPN during HD as compared to no nutritional support. Thus these short-term studies suggest that IDON may provide as safe and at least as effective a way as IDPN for enhancing anabolism in MHD patients.

### Limitations of the clinical trials of intradialytic parenteral nutrition

Virtually all studies that have examined the effectiveness of IDPN are limited by one or more aspects of the experimental design, such as small sample size, and hence, inadequate statistical power, absence of a control group, poorly described inclusion criteria, or the fact that not all of patients receiving IDPN treatment met the criteria for a diagnosis of PEW. Commonly, studies did not describe the dose of dialysis received. The duration of the treatment and follow-up periods were often short. Many trials did not control the intake of food or oral nutritional supplements of the study patients. Occasionally, studies also offered defined amounts of food or oral nutritional supplements to the IDPN-treated or control patients. Due to these limitations, definitive conclusions regarding the effectiveness in IDPN in different patient populations cannot be drawn from the nonrandomized and the randomized studies. Some of the more seminal and influential of the nonrandomized IDPN studies, summarized in Table 40.3, and the randomized trials of IDPN, summarized in Table 40.4, will be reviewed.

### Nonrandomized studies of intradialytic parenteral nutrition

The first report of IDPN in MHD patients was by Heidland and Kult [4]. They administered IDPN to 18 patients undergoing HD thrice-weekly over a 60-week period of study. During the last 90 minutes of each HD session, patients were given 16.7 g of essential amino acids, including histidine, and 250 mL of a mixture of D,L-malic acid, xylitol, and sorbitol. Some nonessential amino acids were added to the above mixture during the first 3 months. In 13 of the 18 patients, therapy was discontinued after 16 weeks. During each dialysis session, close to 100 g of protein in food was also prescribed. However, the intake of food was variable. Serum albumin and total protein levels were reported to increase significantly after 30 weeks of IDPN. Discontinuation of IDPN after 30 weeks resulted in significant fall in serum transferrin concentrations and a decrease in several complement proteins and hemoglobin levels.

Piriano and colleagues reported on 21 MHD patients who had lost at least 10% of their dry weight and were then treated with IDPN for 20 weeks [5]. Sixteen of these patients received IDPN that provided an average of 400 mL of 8.5% essential amino acids and nonessential amino acids with 400 mL of 50% glucose during each dialysis session. The other patients (5 out of 21 patients) were given a solution containing essential amino acids and 50% glucose. These five patients had lost at least 15% of their dry weight. The volume of IDPN provided in these five patients was not provided and the dialysis dose and the comorbid conditions are not clear. In both of these groups, there was no increase in serum albumin levels, and neither group experienced weight gain. However, the patients who did not have hyperparathyroidism and who received the essential and nonessential amino acids did display an increase in body weight.

In 47 MHD patients with severe PEW who received IDPN for 3 months, Bilbrey et al. reported that survivors had a significant increase in serum albumin levels [from  $3.30 \pm 0.38$  (SD) to  $3.71 \pm 0.30$  g/dL,  $P < .001$ ] and transferrin levels ( $165 \pm 37$ – $200 \pm 62$  mg/dL,  $P < .001$ ) [16]. In the nonsurvivors, there was no increase in serum albumin or serum transferrin levels. Duration of IDPN therapy, dialysis dose, and comorbid conditions was not reported.

In a retrospective study, Capelli et al. compared the survival of 50 patients who received IDPN to 31 patients who did not [6]. All 81 patients in the study had low serum albumin levels. At the beginning of the study, oral nutritional supplements and/or nutritional counseling were given for 2 months to all 81 patients in the study. The 31 patients who improved during oral nutritional supplements/nutrition counseling, and therefore did not receive IDPN, served as controls. The patients who did not respond to this nutritional treatment were then given IDPN. The patients treated with IDPN had a body weight that was 10% less than their desirable weight and/or had at least a 10% weight loss. In the control group, low body weights or a history of recent weight loss were not consistently present. The IDPN provided, per dialysis session, a 10%- or 20%-lipid emulsion (200–500 kcal), 50 g of essential amino acids, and a variable amount of D-glucose based on the diabetic status of the patient. Mortality was 48% in controls versus 36% in the IDPN-treated patients ( $P > .05$ ), and time to death in the nonsurvivors was significantly greater in the IDPN-treated patients:  $16.9 \pm 7.9$  (SD) versus  $7.5 \pm 4.2$  months ( $P < .01$ ).

Foulks et al. reported the results of a nonrandomized study of 72 patients with PEW who failed to respond to dietary counseling and who received IDPN [20]. Responders were classified as those who manifested at least a 10% increase in dry body weight or an

increase in serum albumin of  $\geq 0.5$  g/dL while they received IDPN. Mortality was significantly lower in the patients who responded to IDPN. The serum albumin before IDPN was inaugurated was significantly lower in the responders as compared to the nonresponders [ $2.2 \pm 0.7$  (SD) versus  $3.0 \pm 0.8$  g/dL ( $P < .0001$ )]. The body weights were similar in the responders and nonresponders both before and after treatment with IDPN. During the 6 months prior to initiation of IDPN, responders had higher hospitalization rates ( $P < .0001$ ). However, during IDPN therapy, only 52% of responders were hospitalized as compared with 76% of nonresponders ( $P < .0001$ ). The hospitalization rate decreased significantly only in the responders. It is possible that the improved clinical course of the responders was due to the IDPN and the patients' enhanced nutritional status. However, it is also possible that increased morbidity of the nonresponders impaired their ability to respond to the IDPN with a rise in serum albumin of  $\geq 0.5$  g/dL and also led to greater hospitalizations and mortality.

The largest study of IDPN retrospectively compared 1679 MHD patients who received IDPN to 22,517 matched control MHD patients who did not receive IDPN [7]. The IDPN prescriptions were not uniform in the 1679 patients. After adjustment for case mix and predialysis serum creatinine levels, those patients who had baseline serum albumin concentrations  $\leq 3.3$  g/dL and were treated with IDPN, as compared to those who had similar serum albumin levels but who did not receive IDPN, displayed a significant reduction in the odds ratio for death at 1 year. The IDPN-treated patients who had serum albumin levels  $\geq 3.5$  g/dL showed a significant increase in 1-year mortality. This is suggestive that IDPN may be less beneficial in patients with less severe PEW or inflammation. The survival effect of IDPN was greater in those MHD patients who had predialysis serum creatinine levels of 8.0 mg/dL or lower.

In another nonrandomized study, Hiroshige et al. reported results of IDPN therapy in 10 MHD patients who had PEW and were greater than 70 years of age [8]. Eighteen other MHD patients with PEW who refused IDPN were treated with dietary counseling and served as controls. The IDPN-treated group received this therapy for 1 year. The IDPN solutions that they received contained 200 mL of 50% glucose, 200 mL of a 20% lipid emulsion, and 200 mL of 7.1% essential amino acids per dialysis session. There were no major differences in baseline nutritional measures between the two groups. There was a significant increase in serum albumin and transferrin, body weight, triceps skinfold thickness, and midarm muscle circumference in the IDPN-treated group. All of the patients in the control group showed a significant

decrease in each of these parameters. The control group also displayed a decrease in plasma essential amino acid concentrations during the course of the study. In the IDPN-treated group, plasma levels of essential amino acids and some nonessential amino acids increased and 3-methylhistidine levels fell. There were no deaths in the IDPN-treated group as compared to five deaths in the control group ( $P < .02$ ).

### Randomized prospective controlled trials of intradialytic parenteral nutrition

Randomized controlled studies of IDPN are summarized in Table 45.3. A total of 26 MHD patients with PEW were studied by Cano et al. for 12 weeks [9]. A total of 12 patients were randomized to receive IDPN, and 14 patients with a similar degree of PEW did not receive IDPN. The patients receiving IDPN demonstrated a significant increase in body weight, serum albumin and transthyretin (prealbumin) levels, midarm muscle circumference, skin test reactivity, plasma leucine concentrations, and apolipoprotein A-1 levels. The control patients did not manifest an increase in any of these measures. For many of these markers the IDPN group had statistically nonsignificant lower baseline values that could have predisposed to the increase in these values during IDPN. The IDPN solution provided 1.6-g lipid/kg body weight and 0.08 g of nitrogen from essential and nonessential amino acids/kg body weight. Although in the IDPN group plasma apolipoprotein A-1 levels increased, plasma lipid levels did not change. The authors concluded that the high-fat content of the IDPN solutions is effective and safe.

Guarnieri et al. studied 18 MHD patients, most but not all of whom had PEW [10]. Patients were randomly assigned to one of three IDPN treatment regimens according to the amino acid content of the solutions. Patients received either (1) only essential amino acids, (2) a combination of essential and nonessential amino acids, or (3) no amino acids with an isocaloric infusion of 5% glucose. Minerals, vitamins, and trace elements were given with each of the three IDPN treatments. These infusions were given thrice-weekly for 2 months. There was a significant increase in body weight ( $P < .05$ ) only in the patients who received essential amino acids alone. This was the only change in any of the three groups.

In a subsequent study, 21 MHD patients were randomly assigned to receive IDPN for 6 months with essential amino acids (11 patients) or with a mixture of essential and nonessential amino acids (10 patients) as their only nitrogen source [10]. The mean serum

TABLE 45.3 Selected nonrandomized trials of intradialytic parenteral nutrition (IDPN).

Study, first author, year published	Design	Treatment duration	No. w/PEW	Parameters measured	Outcome
Heidland, 1975 [4]	18 pts; 16.75-g EAA, 100 kcal; no control	60 weeks	Most did not	Alb, total protein, complement levels, transferrin	Increase in serum Alb, total protein, transferrin, complement levels after 16 weeks therapy in 13 pts. When therapy was discontinued for 6 weeks, decrease in serum complement and transferrin
Piriano, 1981 [5]	16 pts: 16.5-g EAA + 1 NEAA, 200-g glucose 5 pts: 10.2-g glucose/EAA only	20 weeks	5 (in EAA group lost >15% of usual BW)	BW	In EAA + NEAA group, 8 pts gained >10% BW, other 8 lost weight. Pts in EAA group gained weight if did not have acute illness
Powers, 1989 [16]	18 pts; 250 mL 50% glucose, 250 mL RenAmin	46–165 infusions	All	Weight gain, Alb, TSF, MAMC	Weight gain (12.6 ± 4.9 lb) in 11 of 18 pts. No change in serum Alb
Bilbrey, 1989 [17]	20 pts; 50-g EAA + NEAA, 50-g lipid, 125-g glucose	90 days minimum	All	BW, MAMC	Only MAMC improved
Matthys, 1991 [18]	10 pts; 16.75-g EAA	3 months	All	Quality of life, Hct, BW, degree of edema	BW increased starting from the first month of therapy ( $P < .01$ ). Scoring index of general condition increased ( $P < .01$ )
Bilbrey, 1993 [19]	47 pts; 400 mL 15% AA, 150 mL 70% glucose, 250 mL 20% lipids	90 days minimum	All	Alb, transferrin, mortality	29 survived, 18 died. Survivors had increase in Alb, transferrin. No data on cause of death, dialysis dose
Chertow, 1994 [7]	1679 pts: 1.2 g protein/kg, 15 kcal/kg 22,517 pts: no IDPN	12 months or until death		Alb, URR, odds of death	Decrease in mortality in IDPN-treated pts who had serum Alb ≤ 3.3 g/dL
Capelli, 1994 [6]	50 pts: 50-g EAA, 50-g lipid, 125-g glucose, dietary supplemented (discontinued once IDPN started) 31 pts: dietary supplements	9 months	All had Alb <3.5 g/dL, BW <90% of desirable BW or BW loss >10% over 2 months	Alb, BW, mortality	32 of 50 treated pts and 16 of 31 untreated pts survived. Weight gain in treated survivors, no weight gain in survivors who were untreated. No weight gain in nonsurvivors in either group. 6 months of IDPN before change in weight or serum Alb
Foulks, 1994 [20]	72 pts; 0.64 g N/kg, 3.78 kcal/kg as lipids, glucose	Mean of 159 days in responders, 222 days in nonresponders		Mortality, hosp. rate	Decreased mortality and hospitalization rate in responders
Smolle, 1995 [21]	16 pts; 0.8-g/kg EAA + NEAA	16 weeks		Alb, skin test reactivity, WBC, SCr	NA
Cranford, 1998 [22]	43 pts; 63 g EAA + NEAA, 18.4-g lipid, 92.5 g carbohydrates	6 months		Alb, BUN, hospitalizations	NA
Hiroshige, 1998 [8]	10 pts: 200 mL 50% glucose, 200 mL 7% EAA, 200 mL 20% lipids 18 pts: dietary counseling	12 months	All	BW, BMI, TSF, MAMC, Alb, transferrin, plasma AA profile, mortality	All IDPN-treated pts survived, 5 pts without IDPN therapy died (3 due to sepsis, one due to GI bleeding) during study period
Mortelmans, 1999 [23]	26 pts (16 pts completed study, 10 pts withdrew); 250 mL 50% glucose, 250 mL 20% lipids, 250 mL 7% AA	9 months	All	BW, MAMC, lean body mass, transferrin, serum pre-Alb levels	BW increased ( $P < .05$ ); serum transferrin, transthyretin increased. TSF increased ( $P < .05$ ). No such change in pts who withdrew
Blondin, 1999 [24]	45 pts	6 months	All had mean Alb <3.2 g/dL ± 0.4	Alb, BUN, morbidity, URR, hosp. rate	Decrease in hosp rate ( $P < .05$ ), increase in serum Alb ( $P < .05$ )
Cherry, 2002 [25]	24 pts; 250 or 500 mL 10% AA, 250 mL 50% glucose, 250 mL 20% fat emulsion	4.3 months (mean)	All	Alb, dry BW	Increase in dry BW, serum Alb
Dezfuli, 2009 [26]	196 pts. IDPN no control group	3–12 months	All	Serum albumin	72% of patients had increase in serum Alb. with a mean increase of 0.4 g/dL

Alb, Albumin; BMI, body mass index; BUN, blood, urea, nitrogen; EAA, essential amino acids; HD, hemodialysis; IDPN, intradialytic parenteral nutrition; IV, intravenous; MAMC, midarm muscle circumference; NA, not available; NEAA, nonessential amino acids; PEW, protein-energy wasting; PNA, protein equivalent of total nitrogen appearance; TSF, triceps skinfold; URR, urea reduction ratio.

albumin level was normal at baseline, and the average baseline energy intake prior to IDPN initiation was low. The mean baseline body weight and protein intake were marginally decreased. During IDPN with the essential and nonessential amino acids, but not with the essential amino acids alone, there was a significant decrease in serum albumin levels and an increase in normalized protein nitrogen appearance (nPNA).

The largest prospective randomized study was the French Interdialytic Nutrition Evaluation Study (FineS) [11]. A total of 186 patients, aged 18–80 years, undergoing MHD for more than 6 months were randomly assigned to receive IDPN ( $n=93$ ) or to not receive IDPN ( $n=93$ ). IDPN was given during dialysis sessions for 1 year. Both the IDPN-treated group and the control group received oral nutritional supplementation as part of the study design. Patients included in the study had at least 2 of the following indicators of PEW: (1) edema free weight loss of greater than 10% over the previous 6 months, (2) serum albumin  $<3.5$  g/dL, (3) body mass index  $<20$  kg/m<sup>2</sup>, and (4) serum transthyretin  $<30$  mg/dL. The exclusion criteria were (1) single-pool Kt/V  $<1.2$ , (2) TPN received within the 3 months preceding the study, (3) severe comorbid conditions that adversely affect 1-year survival, (4) less than 12 hours of dialysis treatment per week, (5) fasting serum triglyceride levels  $>300$  mg/dL, and (6) hospitalization at the time of randomization. The nutritional intake, including energy intake, from all sources was monitored at baseline and at 3, 6, 12, 18, and 24 months after the onset of IDPN. The follow-up period was up to 2 years.

At months 3, 6, and 12, IDPN provided with each HD session, respectively, the equivalent of  $6.6 \pm 2.6$  (SD),  $6.4 \pm 2.1$ , and  $6.1 \pm 2.2$  kcal/kg and  $0.26 \pm 0.08$ ,  $0.25 \pm 0.09$ , and  $0.24 \pm 0.10$  g/kg of amino acids. To estimate the time-averaged daily dose, these estimates should be multiplied by 3 (three hemodialyses per week) and divided by 7 (the number of days in the week). At months 3, 6, and 12, oral supplements provided  $5.9 \pm 2.6$ ,  $5.8 \pm 2.5$ , and  $5.6 \pm 2.7$  kcal/kg/day and  $0.39 \pm 0.18$ ,  $0.38 \pm 0.18$ , and  $0.37 \pm 0.18$  g protein/kg/day. There was patient-to-patient variability as well as variability among HD centers with regard to the intake of nutrients from the IDPN and from spontaneous eating.

The results indicated no statistical difference in mortality, hospitalization rates, and indicators of PEW between the patients assigned to IDPN and the control patients. Both treatment groups showed no change from baseline in Karnofsky scores, nor was there any difference between the two groups in the change in these scores from baseline. The authors noted that although this was the largest prospective randomized trial to date, it was still

underpowered. Since both groups received oral nutritional supplements, it is not unlikely that the failure to demonstrate any differences in outcome between the IDPN and control groups may have been due to the substantial intake of oral nutritional supplements that both groups received. Those patients in both treatment arms who had an increase in serum transthyretin to greater than 30 mg/L within the first 3 months of the trial displayed an approximately 50% decrease in mortality at 2 years.

The most recent multicenter randomized trial was conducted by the German IDPN-Trial group [12]. A total of 107 MHD with PEW were studied to assess the impact of IDPN on prealbumin and other measures biochemical and clinical measures of nutrition. Patients who were randomized to the intervention group received IDPN three times per week for 16 weeks followed by a treatment-free period of 12 weeks and nutrition counseling. The main inclusion criteria included moderate-to-severe PEW (Subjective Global Assessment score B or C), MHD for more than 6 months, the presence of two out of the following three criteria: serum albumin  $<35$  g/L, serum prealbumin  $<250$  mg/L, and phase angle  $\alpha <4.5$  as determined by bioelectrical impedance analysis). Nutrition counseling was started at the time of randomization. The standardized control group (nonintervention group) received nutrition counseling only. The key outcome measure was the effect of IDPN on serum prealbumin levels. A total of 83 patients were studied in the final analysis out of which 39 patients were in the IDPN group and 44 patients were in the control group.

This trial demonstrated significantly improved prealbumin levels at 16 weeks of IDPN treatment [mean change in serum prealbumin:  $+26.31 \pm 58.66$  (SD) mg/L in the IDPN group;  $-1.84 \pm 49.35$  mg/L in the controls; IDPN vs controls,  $P=.02$ ]. This response was sustained during a treatment free follow-up period of 12 weeks. An  $\geq 15\%$  increase in serum prealbumin was observed at 4 weeks in 41% of the 39 patients in the IDPN group versus 20.5% of the 44 patients in the control group. No data were provided to justify the greater than or equal to 15% increase in serum prealbumin from baseline as a threshold for a responder to IDPN, and this value did not seem to be prespecified in the protocol. The mean improvement in serum prealbumin ( $+26.31$  mg/L) levels in the IDPN group did not reach the threshold of  $>30$  mg/L that was shown to be associated with reduction in mortality in the FineS study. There was also a trend toward more patients who received IDPN, as compared to controls, who attained a significant increment in serum prealbumin concentrations of

$\geq 30$  mg/L at week 16 (48% in the IDPN treatment group vs 31.8% in the control group,  $P = .1164$ ). Serum albumin levels in the IDPN group did not improve significantly, and the authors of the study believed this was due to the short duration of IDPN treatment and because the sample size was not powered enough to detect a difference. A post hoc analysis showed an inverse correlation between serum C-reactive protein (an indicator of inflammation) and albumin levels that could account for the unexpected decrease in serum albumin in some patients.

### **Advantages and disadvantages of intradialytic parenteral nutrition**

Advantages to IDPN include the nutritional support that it provides to patients with each dialysis session independent of their appetite, anorexia, or gastrointestinal function. Since the nutrition is given intravenously, the compliance of the patients or the willingness or the ability of the patient to cooperate does not materially affect this aspect of their nutritional intake. There is no need for an additional vascular access, because IDPN is given through the patient's preexisting access. The nutrient composition and the quantity of IDPN can be controlled and modified as needed. The excess fluid administered with intravenous infusions can be removed as it is infused during HD and should not add to the water load of the patient.

Disadvantages to IDPN therapy as it is usually given are that the nutritional supplements can only be given for about 9–12 hours weekly because it is given only during HD. Therefore IDPN, since it is generally provided three times weekly, cannot be the sole source for adequate nutrition. Since IDPN is given intravenously, it presents a nonphysiological circumvention of the normal gut–nutrient interactions. Hence, it does not contribute to the direct trophic effects of oral or enteral nutrition on the gastrointestinal tract. There is rapid clearance of nutrients from the blood with IDPN—much faster than is found with oral or enteral feeding into the stomach. Usually, IDPN adds significantly to the costs of dialysis therapy.

### **Adverse effects of intradialytic parenteral nutrition**

Adverse events that have been reported include nausea, hyperglycemia, muscle pain, and post-IDPN reactive hypoglycemia. However, the published data on adverse effects of IDPN are limited; about 12%–14% of patients in two randomized controlled trials experienced

such events [11,12]. It is difficult to analyze the clinical significance of adverse effects from IDPN in these published studies because the duration of treatment was short and the follow-up was limited.

### **Indications for intradialytic parenteral nutrition**

In patients who are able to eat, there is a consensus that adequate nourishment should be provided using the oral route with normal food with or without food supplements. Tube feeding should be considered for patients who are unable to maintain adequate protein–energy status solely by eating. Tube feeding is more physiologic than intravenous feeding and can have valuable trophic effects on the gastrointestinal tract. Tube feeding is also safe and inexpensive. For MHD patients who cannot be adequately nourished by oral intake and tube feeding or when these routes of nourishment are not safe for a patient, IDPN should be considered. IDPN cannot be used as the sole source of nutrition for patients who undergo MHD only thrice-weekly. There are some MHD patients whose nutritional needs cannot be met by either oral intake or tube feeding combined with IDPN, and they may require TPN. Definitive indications for IDPN are difficult to identify, because benefits regarding morbidity and mortality have not been shown conclusively in randomized, prospective trials of IDPN. There are no randomized prospective clinical trials of IDPN that have the combination of adequate sample sizes, sufficiently long duration of study, appropriate key outcome measures, and an experimental protocol with the necessary rigorous design (Table 45.4). It is important to note that despite the fact that there are no adequately powered prospective randomized clinical trials, the data that are available so far support the thesis that enteral feeding or IDPN benefit survival in MHD patients with PEW [13].

### **Considerations for intradialytic parenteral nutrition prescription by health-care workers in the United States**

In the United States the approval for the initiation of IDPN for an MHD patient is based on the insurance coverage of the particular patient, although the coverage criteria are likely to change. Patients with Medicare insurance may have their IDPN covered by the Part D program of Medicare if they are outpatients. For hospitalized patients, IDPN is covered under Medicare Part A. The criteria that Medicare currently uses to approve initiation of IDPN coverage are

TABLE 45.4 Randomized prospective trials of intradialytic parenteral nutrition (IDPN).

Study, first author, year published	Design	Treatment duration	Number with PEW	Parameters measured	Outcome
Wolfson, 1982 [2]	8 pts. EAA + NEAA + glucose solution versus normal saline	NA	NA	Amino acid losses into dialysate with and without IDPN	There was a small increase in amino acid losses into dialysate during IDPN
Toigo, 1989 [27]	11 pts: 26.5-g modified EAA 10 pts: 24-g EAA + NEAA	6 months	None	Nerve conduction velocity, Alb	Decrease in serum albumin in EAA + NEAA group
Cano, 1990 [9]	12 pts: 0.08-g N/kg (per HD session) from EAA + NEAA, 1.6 g/kg (per HD session) lipids 14 pts: no intervention	3 months	All	BW, appetite, MAMC	Increase in calorie (9 kcal/kg/d) and protein intake (0.25 g/kg/d) in IDPN-treated pts
McCann, 1999 [28]	19 pts; 70% glucose, 15% amino acids, 20% lipids	11 weeks	NA	Delivered Kt/V, URR	Reduction in delivered Kt/V in pts who received amino acid-containing IDPN
Navarro, 2000 [29]	17 pts	3 months	NA	NA	Positive net balance of amino acids. Increase in PNA, serum Albumin transferrin
Cano, 2006 [30]	17 pts: olive oil-based IV lipid emulsion 18 pts: soybean oil-based IV lipid emulsion	5 weeks	NA	NA	Both groups showed similar improvement in nutritional status, plasma lipid, oxidative and inflammatory parameters
Cano, 2007 [11]	IDPN: 89 pts Control: 93 pts	12 months	All	Primary endpoint, all-cause mortality; secondary endpoints, hosp. rate, BW, Karnofsky score, BMI	No difference in hospitalization rate or mortality between two groups
Thabet, 2017 [31]	20 pts. IDPN + IV vitamins compared to 20 pts received IV vitamins alone	6 months	All Baseline serum albumin was 3.02 and BMI was 19		
Marsen, 2017 [12]	39 pts: IDPN + standard nutrition counseling 44 pts received standard nutrition counseling alone	16 weeks	All	Prealbumin, transferrin Subjective global Assessment (SGA) Score SF-12 Health-related short-term quality of life survey	IDPN given three times a week resulted in increase in greater or equal to 15% increase in serum prealbumin over baseline at week 4 in 41% of the 39 patients

Note: Only clinical trials with eight or more patients are listed. *Alb*, Albumin; *BMI*, body mass index; *EAA*, essential amino acids; *HD*, hemodialysis; *PEW*, protein-energy wasting; *IDPN*, intradialytic parenteral nutrition; *IV*, intravenous; *MAMC*, midarm muscle circumference; *NA*, not available; *NEAA*, nonessential amino acids; *PNA*, protein equivalent of total nitrogen appearance; *URR*, urea reduction ratio.

summarized in Box 45.1. The coverage of IDPN by Medicaid (insurance coverage by the state for qualified individuals) is not uniform. Many state Medicaid programs in the United States do cover IDPN. The private insurance carriers loosely follow Medicare criteria for approval of IDPN, but coverage for IDPN is uneven and some costs may be transferred to the patient. Most Health Maintenance Organizations do not provide coverage for IDPN. Medicare, Medicaid, and most commercial private insurance carriers recommend that IDPN is to be discontinued if serum

albumin is  $>3.8$  g/dL for more than 3 consecutive months.

## Nutritional hemodialysis and intraperitoneal nutrition

### Nutritional hemodialysis

Adding essential and nonessential amino acids to hemodialysate will result in an uptake of amino

## BOX 45.1

**United States Medicare Part D criteria for approval to initiate IDPN (intervention for malnutrition: patient qualification criteria)**

1. Patient given intensive dietary counseling, emphasizing the need for increased protein and/or calorie intake, for a minimum of 1 month with no evidence of clinical improvement (i.e., rise in serum albumin and/or weight)
2. Initiation of oral supplementation attempted with no improvement in and/or weight gain after 1–2 months
3. Evidence of continued protein malnutrition as documented by:
  - A. A 3-month average serum albumin <3.5 g/dL
  - B. Progressive decline in serum albumin over 3 months to <3.5 g/dL
  - C. nPNA (nPCR) <0.8 g protein/kg/day or documentation of inadequate protein intake or  
Evidence of continued calorie malnutrition as documented by:
    - A. Current weight <90% of ideal body weight
    - B. BMI < 18 or
    - C. Weight loss greater than 5% over three months.
4. Recommendation by physician for prescribing IDPN therapy

acids into blood, which can be substantial [12]. When 139 g of an amino acid mixture is added to the total dialysate concentrate used during a typical 4-hour HD session, there is a net transfer of 39 g of amino acids from dialysate into the patient during the routine HD [12]. When 46 g of a mixture of 20 essential and nonessential amino acids are added to the dialysate concentrate, the plasma amino acid concentrations remain similar to those in the plasma of fasting patients suggesting that there is little or no net transfer of amino acids to or from the patient. The increase in osmolality in the hemodialysate is not a substantial limiting factor when adding glucose with amino acids to hemodialysate, since even adding glucose monohydrate to create a dialysate glucose concentration of 500 mg/dL will only add about 28 mosm/L to dialysate osmolality.

Although it is possible to provide the patient's daily need for essential and nonessential amino acids in the hemodialysate, it is not feasible to provide all of the patient's energy requirement through the hemodialysate. The total energy intake from the hemodialysate will be grossly inadequate for the patient's daily needs. Of course, the needed glucose and lipids can be either ingested or infused intravenously during HD. At the least, providing amino acids during HD should eradicate the catabolic effects of amino acid losses during HD that patients will sustain when they fast during this procedure [3]. Theoretically, adding amino acids to hemodialysate should be a less expensive treatment than IDPN for providing adequate amino acid nutrition during HD, because the amino acids do not have to be

sterilized in solution. Lowering the hemodialysate flow rate has been done by some investigators to increase the fractional extraction of amino acids and glucose from the dialysate into blood [14]. The advantage of this approach is the increased efficiency and, hence, reduced cost of the quantities of amino acids taken up from the dialysate, but the disadvantage is the decreased efficiency of dialysis.

### Intraperitoneal nutrition

The addition of amino acids to peritoneal dialysate appears to increase protein synthesis during peritoneal dialysis and raise serum or plasma concentrations of several proteins and amino acids [15]. By substituting amino acids for some of the glucose in peritoneal dialysate, this treatment also allows for a reduction in the dialysate glucose concentrations, which is often of metabolic benefit to the patient, with little or no loss of the osmotic pressure. Generally, a mixture of essential and nonessential amino acids is added to a typical peritoneal dialysate solution that may be further modified to reduce the glucose concentration. The final composition of the dialysate will generally contain a concentration of 1.1% amino acids. This solution is used for one or two of the peritoneal dialysate exchanges each day. To ensure uptake of about 80% of the amino acid content, a dwell time of 4–6 hours is recommended.

Again, to prevent excessive osmolality of the dialysate solutions, the energy that can be provided from these solutions is not substantial. When patients receive intraperitoneal nutrition, they should be encouraged to consume a

nutrient intake or undertake tube feeding that provides at least most of their needs for energy and most other nutrients. However, care must be taken to prevent an excessive load of amino acids and protein from the combined intakes of intraperitoneal and oral or enteral nutrition. High serum urea levels, metabolic acidosis, and even some uremic symptoms can develop from such intakes.

## Introduction

Acute kidney injury (AKI), a common complication in the intensive care unit (ICU) associated with high mortality rate [1], more often occurs in the context of multiple organ failure syndrome than as an isolated condition [2]. As a consequence, metabolic and nutritional requirements of patients with AKI in the ICU are affected not only by the acute uremic state, but also by the underlying comorbidities and associated complications. Approximately 4%–6% of all critically ill patients with AKI will require some form of renal replacement therapy (RRT) during their ICU stay [3,4]. Currently, continuous RRT (CRRT), along with prolonged intermittent RRTs (PIRRTs) such as sustained low-efficiency dialysis (SLED), represents the primary choice in critically ill patients; in fact, these RRT modalities allow for a better hemodynamic stability with efficient fluid removal and metabolic control [5]. By lowering the dialysis or replacement-fluid flow and extending the duration of treatment to often more than 24 hours, rates of solute clearance, osmolality shift, and ultrafiltration rate are significantly reduced, resulting in better hemodynamic tolerability and clinical stability. Because of the efficiency of CRRT, nutritional losses can be very important, thus requiring a close coordination between nutritional support and CRRT itself [2,6,7].

In this chapter, nutritional implications of CRRT will be reviewed, with emphasis on nutrient balance, and the recommendations on nutritional support in patients with AKI in the ICU requiring CRRT will be discussed.

## Continuous renal replacement therapy overview

CRRT is widely considered one of the preferred RRT modalities for critically ill patients with renal dysfunction (AKI or critically ill patients with previous end-stage renal disease (ESRD) on maintenance hemodialysis), especially in cases complicated by hemodynamic instability and/or acute brain injury. Running in a continuous manner even for more than 24 hours, CRRT allows slower fluid and solute removal, thus obtaining a better hemodynamic tolerance and reducing the risk of rapid osmolality shifts. Veno-venous modalities of CRRT are currently the standard of care. Several modalities of CRRT are available (Table 46.1), each primarily depending on the mechanism used for solute transport, diffusion, and convection (Fig. 46.1), which can be used separately or combined. In the case of diffusion, dialysis fluid routinely runs counter-current to the blood flow inside the filter, creating a concentration gradient that will allow for solutes to diffuse through the hemofilter membrane. In this case, solute removal is mainly dependent on molecular weight, with smaller molecules being removed more easily than larger molecules. Continuous veno-venous hemodialysis (CVVHD) is the continuous modality that exclusively applies diffusion. Convection generates a much higher volume removal (ultrafiltrate) across the hemofilter by applying a high transmembrane pressure gradient, which drags predetermined fluid volume and solutes with it. In this case, both small- and medium-size solutes are effectively removed. Because of high fluid removal (solute clearance is proportional to volume removed), replacement fluids are needed to restore volume and

electrolytes. Continuous veno-venous hemofiltration (CVVH) is the modality that relies only on convection. The contemporary adoption of both solute removal techniques is a characteristic of continuous veno-venous hemodiafiltration (CVVHDF), a RRT modality that requires the use of both dialysis and replacement fluids. Dialysis and replacement fluids contain electrolytes and buffers at different concentrations. In CVVH the adoption of prefilter replacement fluid dilutes the actual plasma concentration entering the hemofilter, thus reducing the effective clearance, but in parallel may prolong filter life reducing the risk of clotting [8]. With conventional intensity CVVH, the differences in small solute

clearance with pre- or postfilter replacements are negligible [9]. Independently from the dialysis modality, the most recent international guidelines on AKI recommends prescribing an effluent volume of at least 25 mL/kg/h, to achieve an effectively administered dialysis dose of 20 mL/kg/h, taking into account all treatment interruptions and downtime (i.e., temporary and unscheduled suspension of CRRT administration) [10]. Clinical trials have not demonstrated any advantage correlated with higher RRT doses (more than 35–40 mL/kg/h), emphasizing on the contrary the possible clinical disadvantages related to deficiency of vitamins, micro- and macronutrients lost in the effluent, as well as the risk for inadequate

antibiotics levels [11,12]. In this regard, because most nutritional substrates are small and have a sieving coefficient, defined as the ratio of ultrafiltrate to plasma solute concentration, that approximates 1, their clearance is affected mainly by effluent rate, which makes the difference in nutrient losses between various modes of CRRT negligible. Other modalities of RRT, commonly denominated PIRRT or SLED, are characterized by 8- to 12-hour sessions and share most advantages of both the conventional intermittent RRT and CRRT [13]. PIRRTs, predominately based on diffusive mechanism for solute transport, have been shown to be safe and convenient, providing an excellent control of electrolytes and fluid balance [14]. Usually, the modality of CRRT selected usually depends on institution preference, local experience and logistics, fluid status, and metabolic/electrolyte abnormalities.

### Continuous renal replacement therapy's components and their implications for nutritional support

When discussing the nutritional effects of CRRT, it is important to understand how CRRT evolved. Considering recent advancements in CRRT technology in the last decade [15], the factors that have a recognized impact on nutrition are replacement and dialysis fluids, and the choice of the anticoagulation modality.

#### Replacement and dialysate fluids

Replacement fluids are used to restore electrolytes and volume when CRRT modalities that exclusively or in part are based on convection are applied (CVVH and CVVHDF). In predominantly diffusion modalities (CVVHD and CVVHDF), dialysis fluids are used to establish a concentration gradient across the filter membrane.

A variety of commercially solutions are available, with different electrolytes and buffer compositions (Table 46.2). The selection of replacement or dialysate fluid is crucial to optimize the CRRT prescription and it usually depends on patients' metabolic, electrolyte, and acid-base profile. The different buffers utilized in CRRT fluids include bicarbonate or bicarbonate yielding substrates such as acetate, lactate, and citrate. Some of the dialysate and replacement fluids commonly used in the dialysis/hemofiltration procedures may provide energy substrates in the form of acetate, lactate, citrate, and glucose (Table 46.3). Lactate provides 0.33 kcal/mmol (3.7 kcal/g), and because only 6% of the infused lactate will be eliminated during CRRT, the amount of extra energy provided can be

important. Assuming a buffer solution containing 40 mmol/L of lactate running at 2 L/h, this alone may account for as much as 500 kcal/day. Currently, bicarbonate-based solutions are preferred over lactate-based solutions, due to better control of acidosis, reduced lactate accumulation, and better hemodynamic tolerance [16,17]. Replacement and dialysis solutions also contain a variable amount of dextrose, usually ranging from 0 to 110 mg/dL. This may impact the amount of energy gain, if high dextrose concentration replacement/dialysate fluids are used, or net energy loss if glucose-free solutions are used instead; thus it should be taken into account when prescribing nutrition therapy.

#### Anticoagulation

During CRRT and PIRRT, an anticoagulation strategy is required to avoid RRT interruption and blood losses/transfusion need due to coagulated filter and/or extracorporeal circulation. Currently, continuous infusion of unfractionated heparin still remains the most adopted anticoagulation strategy for the extracorporeal circulation of RRT, despite the increased bleeding risk associated with this therapeutic approach. Several alternative strategies have been tested focusing at providing the anticoagulation of the extracorporeal circuit only, that is, aiming at the *regional anticoagulation* of the extracorporeal circulation without interfering with the systemic patient's hemostasis. Above all the possible anticoagulation methods, the suggestion from the most recent Guidelines on AKI, supported by several randomized trials designed to compare different strategies [18–24], is to use regional citrate anticoagulation (RCA) for all patients with and without an increased bleeding risk who do not have contraindications for citrate [10]. During RCA, citrate is infused into the inflow limb of the extracorporeal circuit at rates proportional to blood flow, providing the anticoagulation of the hemofilter and circuit lines by chelating ionized calcium in the blood, thereby blocking the clotting cascade at multiple steps. The citrate infusion rate is modulated to reach a concentration in the hemofilter around 2.5–3 mmol/L, which corresponds to ionized calcium levels in the extracorporeal circuit of 0.3–0.4 mmol/L. Because calcium–citrate complexes are characterized by high diffusive/convective clearance, with a significant amount of calcium being lost in the effluent fluid, an infusion of calcium (as chloride or gluconate) is generally required, to maintain the systemic ionized calcium levels within the normal range. The amount of citrate and calcium–citrate complex returning to the patient represents the metabolic load of citrate and corresponds to the difference between the citrate infused and the amount lost in the effluent.

This metabolic load, commonly around 12–20 mmol/h, usually is rapidly metabolized through the Krebs cycle in the liver, skeletal muscle, and kidney, with the indirect production of 3 mmol of sodium bicarbonate for each 1 mmol of citrate. Indeed, in course of RCA the amount of bicarbonate derived from citrate metabolism provides the buffer supply to the patient, along with bicarbonate already present in the replacement and dialysis fluids. Commercially available RCA solutions may be classified on the basis of citrate concentration in *high-concentration citrate solution* (hypertonic in sodium) and *low-concentration citrate solutions* (isotonic in sodium) (Table 46.4). While the first ones are generally preferred in course of CVVHD and SLED, modalities mostly based on diffusive clearance, the low-concentration solutions can be used in course of CVVH, CVVHDF, and some variants of SLED (e.g., SLED-f). According to the principles of buffer balance in CRRT, the hypertonic solutions should be preferably combined with customized dialysis solutions characterized by low sodium and bicarbonate concentration, to avoid hypernatremia and metabolic alkalosis. In protocols adopting the isotonic citrate solutions, a high flow rate of the citrate-based fluid is needed to achieve the target citrate levels in the extracorporeal circuit blood and, as a consequence, citrate-buffered replacement solution will significantly contribute to the total dialysis RRT dose. In this regard, it is important to consider all of the possible electrolyte and acid–base abnormalities resulting from the fact that anticoagulation prescription for CRRT is strongly related to dialysis depurative effect. To achieve a correct balance, it is possible to combine the citrate solution with dialysis or replacement fluid characterized by adequate electrolyte

and buffer concentration and, if needed, to provide an external continuous or extemporaneous supplementation. Several protocols of RCA are now routinely and safely applied in clinical practice, providing a CRRT prescription tailored on electrolyte and acid–base patient's status. As previously anticipated, the amount of energy delivered from fluids composition in course of RRT must be taken into account when estimating the nutritional needs of the patient with AKI. Indeed, independently of the kind of solution selected, citrate represents a source of energy, providing 0.59 kcal/mmol, which means approximately 150–280 kcal/24 h for a citrate load of 11–20 mmol/h [25,26]. Furthermore, by using Anticoagulant Citrate Dextrose Solution A (ACD-A), which contains 2.5% dextrose, an additional caloric load may derive from dextrose metabolism (0.73 kcal/mmol), delivering 350–600 kcal/24 h.

## Implications for nutritional support

### Energy requirements

The accurate determination of protein and energy needs is important in the clinical setting of AKI in the ICU, because both over- and underfeeding may occur, which are associated with poor outcomes [2,27]. In particular, significant underfeeding has been recently documented in a recent reanalysis of data from a large cohort of patients with AKI from the RENAL study, whose average daily calorie and protein intake was, respectively, 867 kcal and 34.8 g [28]. On the other hand, energy intake should never exceed actual energy requirements, since overfeeding is much more

deleterious for critically ill patients than moderate underfeeding, particularly because of the increased hyperglycemia risk and insulin need, possible electrolyte disorders, and fluid overload [2]. In patients with AKI an energy provision of 40 kcal/kg/day via parenteral nutrition was associated with more severe metabolic complications, such as hypertriglyceridemia and hyperglycemia than lower intakes (30 kcal/kg/day), without any positive effect on nitrogen balance [29].

The gold standard for measuring individual caloric needs is represented by indirect calorimetry (IC), a noninvasive method allowing resting energy expenditure (REE) assessment based on oxygen consumption and carbon dioxide production measurements in the exhaled air [30]. In critically ill patients, REE measured by IC is in general considered for nutritional prescription. Unfortunately, IC measurements are not widely used in daily practice, even in the ICU setting [30].

Guidelines on renal and ICU patients [31–34] recommend the enteral route as the first choice for nutrition support in patients who are unable to eat, which is the case for the majority of ICU patients. Parenteral nutrition is indicated in AKI when the gastrointestinal (GI) tract cannot be used or when enteral nutrition (EN) is inadequate to reach nutrient intake goals. An energy prescription of 20–25 kcal/kg/day is currently recommended during the acute phase of the disease, and 25–30 kcal/kg/day during recovery. However, in many cases it is not mentioned if the actual, preadmission, or ideal BW should be considered. Considering that patients with AKI frequently have fluid overload and suffer sudden fluid shifts related to RRT, it is even more difficult to define the reference body weight (BW) to be used to estimate energy expenditure (EE) using predictive equations. A recent study in 205 critically ill patients compared the REE obtained using the Harris–Benedict equation using three different reference body weights (actual, ideal, and predicted BW) with REE measured by IC. It was found that REE estimated using the Harris–Benedict equation, regardless of the reference body weight used, did not agree with REE obtained by IC measurement, and Bland–Altman analysis showed wide limits of agreement [35]. Only two observational studies were performed in critically ill patients with AKI comparing IC determination of EE with EE based on kcal per kg BW and other predictive equations, including the Harris–Benedict equation [36,37]. Both studies agreed that EE calculation with formulas had low precision, wide limits of agreement and often under- or overestimate the true EE, depending on the BW used for the calculations. Thus despite being a very simple way to predict EE, this approach is likely to increase the risk of both over- and underfeeding in ICU patients with AKI.

Finally, whether only one IC measurement at the beginning of recovery is enough to tailor nutritional

prescription during ICU stay is still an open question. In one study, there was no difference between energy measurements performed at the beginning of ICU stay and within 1 week, nor within 48 hours, despite a vast majority of patients (68%) presenting with differences greater than  $\pm 10\%$ , which could be clinically relevant [36]. A retrospective study on 1171 critically ill patients found a significant ( $P < .0001$ ) between-day difference; however, the difference lost significance after excluding the first 2 days of hospitalization [38]. An expert position paper on IC in critically ill patients [30] stated that energy expenditure of critically ill patients is very dynamic and depends on the phase and the severity of illness, treatment, and extended bed rest. The same concept holds true for AKI patients [33,34]. Thus it is recommended that, whenever the clinical condition of the patient is changing, IC should be repeated.

### Carbohydrate gain and loss during continuous renal replacement therapy

When prescribing enteral or parenteral nutrition in the ICU, clinicians should routinely assess for possible sources of “hidden calories.” Calories may be provided by dextrose-containing fluids administered via intravenous medications, during bolus or continuous crystalloid infusions, when using propofol or clevidipine for sedation, in addition to the potential energy gain via fluids used during CRRT. Except for propofol and clevidipine, which provide energy in the form of lipids, other “hidden sources” of energy derive from carbohydrates. Carbohydrates sources during CRRT are described in Table 46.3.

Depending on the protocol used, energy gain can be substantial. When standard modalities of CRRT with trisodium citrate solutions are employed, an estimated 300–500 mmol/day of citrate reaches the patient’s bloodstream, providing approximately 300 kcal/day [39]. However, during other modalities of CRRT based on the use of Anticoagulant Citrate Dextrose Solution A (ACD-A) as an anticoagulant and in some cases lactate as a buffer, the estimated daily energy load derived from the citrate, glucose, and lactate can range from 500 to 1200 kcal/day [26,40,41]. A recent study confirmed the potential caloric gain during CRRT [42]. Using a CVVH protocol based on the most recent guidelines on RCA, the average caloric uptake from CRRT was 513 kcal/day (218 kcal/day from citrate and 295 kcal/day from glucose). However, the impact of glucose-free replacement fluids was not assessed, which could actually have reduced the amount of caloric gain.

It is important to understand how the glucose content of fluids employed during CRRT may impact the delivery of extra energy. As a matter of fact, glucose-

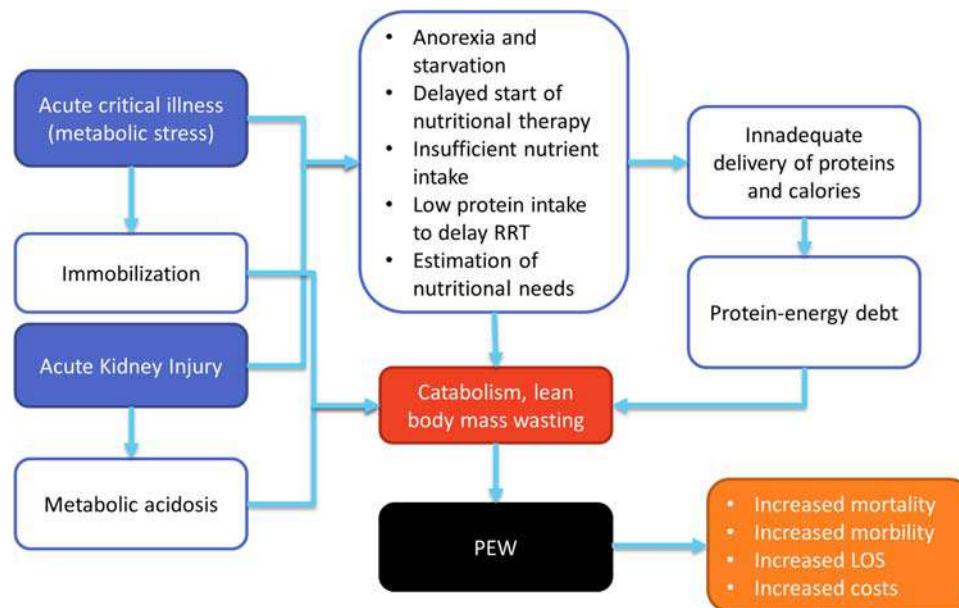

FIGURE 46.2 Pathogenesis of muscle wasting in critically ill patients with AKI. AKI, Acute kidney injury.

free replacement fluids may contribute to glucose losses, since the lost glucose in the effluent is left unreplaced. On average, 40–80 g/day of glucose can be lost, if glucose-free CRRT fluids are used [43,44]. More important losses are usually associated with the use of higher effluent volumes and the presence of hyperglycemia and can significantly reduce the effective calorie delivered through the nutritional support [43]. In vitro models of different modalities of CRRT confirmed the effect that glucose-free fluids have on final glucose balance [45]. An equation was derived to calculate glucose losses for any method of CRRT when glucose-free fluids are used, and the blood flow rate is 200 mL/min:

$$y = 0.81 [Q_D \times EC \times (G_{Pre} - G_D) + Q_{UF} \times EC \times G_{Pre}] + 4.16 \quad (46.1)$$

where  $y$  is the total kcal/day removed;  $Q_D$  is the dialysis flow rate (L/h);  $EC = 1$  (extraction coefficient =  $E_f/Pre$ , where  $E_f$  is the concentration in effluent leaving the dialysis filter and  $Pre$  is the concentration in the prefilter blood);  $G_{Pre}$  is the glucose concentration prefilter (mg/dL);  $G_D$  is the glucose concentration in the dialysate (mg/dL); and  $Q_{UF}$  is the ultrafiltration rate.

The ideal fluid glucose concentration is unknown. In critical illness, intensive plasma glucose control (80–110 mg/dL or 4.4–6.1 mmol/L) with insulin leads to increased hypoglycemic events [46–49] and increased patient mortality [48], compared to conventional control (up to 200 mg/dL or 11.1 mmol/L). The target plasma glucose range is therefore recommended to be 144–180 mg/dL (8–10 mmol/L) [27,50–52]. In addition, CRRT is associated with an independent risk of

hypoglycemia [53]. Using a fluid with a similar glucose content to optimal plasma level may help to prevent hypoglycemia and glucose variability, which are associated with increased mortality [54,55].

In conclusion, energy excess provided by RRT could be partially avoided by using protocols based on lower citrate concentrations [45], bicarbonate as a buffer, citrate solutions other than ACD-A in lower doses and without glucose [39], and glucose-free replacement or dialysate fluids. Alternatively, PIRRT modalities, such as SLED, easily allow increased citrate removal by the effect of diffusive treatment itself [56]. Notably, when citrate-based anticoagulation is not used, energy loss may occur when glucose-free fluids are employed and the glucose removed in the effluent liquid is not replaced. Also in any case, the energy excess provided by citrate, lactate, and glucose in RRT solutions should be factored in the patient's cumulative energy balance, and also for the purpose of glycemic control [27].

## Proteins and amino acids

Critically ill patients in general and AKI patients in particular are characterized by an increased protein catabolism and turnover, with a redistribution of amino acids from lean body mass (mainly the skeletal muscle) to other tissues involved in the acute response, causing muscle wasting and negative nitrogen balance [2]. Multiple factors contribute to the increased catabolism of critically ill patients on CRRT (Fig. 46.2), the amino acid losses in the ultrafiltrate, and dialysis fluid being a key factor for worsening of this condition [2,43,57–63]. The

1. **TNA = UNA + other nitrogen appearance**
  - TNA: total nitrogen appearance over 24 hours
  - UNA: urea nitrogen appearance over 24 hours
2. **UNA = ([UN]<sub>urine</sub> x UV) + ([UN]<sub>effluent</sub> x EV) + change in body UN content**
  - [UN]<sub>urine</sub>: urea nitrogen concentration in urine
  - [UN]<sub>effluent</sub>: urea nitrogen concentration in CRRT effluent
  - UV: urine volume over 24 hours
  - EV: CRRT effluent volume over 24 hours
3. **Change in body UN content over 24 hours =**  

$$([BUN] \times \text{total body water})_{\text{current day}} - ([BUN] \times \text{total body water})_{\text{day before}}$$
  - [BUN]: blood urea nitrogen concentration
  - total body water  $\approx 0.6 \times$  body weight (males)  
or  $0.5 \times$  body weight (females)

4. **Other nitrogen appearance includes:**
  - Amino acid nitrogen loss in CRRT (estimated 10% of TNA)
  - Creatinine nitrogen, other protein losses, skin losses, and gastrointestinal losses (not routinely measured)
  - UNA is thus estimated at 65–75% of TNA  
→ **Therefore TNA  $\approx$  UNA  $\div$  0.7**
5. **Nitrogen balance = nitrogen intake – TNA**
  - Nitrogen intake =  $0.16 \times$  daily protein intake (nitrogen content of protein is about 16%)
6. Conversely to the above,  
**PCR = TNA x 6.25**
  - PCR: protein catabolic rate

*The above equations are limited by the various assumptions, and serve only to provide a clinically useful approximation of nitrogen balance and protein catabolic rate.*

**FIGURE 46.3** Available equations for the estimation of protein catabolic rate.

factors related to the CRRT prescription, which will determine how many amino acids will be lost, include the modality of CRRT (convection, diffusion, or both), the blood and dialysis fluid flow rate, effluent rate, and membrane properties of the filter used [62,64]. In addition, many amino acids are low molecular weight substances with a sieving coefficient near 1.0; thus amino acids such as cysteine, arginine, alanine, and glutamine can be readily filtered from the blood into effluent [58,59]. Currently, with the increased efficiency of CRRT technology, allowing higher blood flow rates and increased effluent removal, it is possible to estimate that the actual amino acid losses of patients on CRRT are much more than those reported in the earlier studies [43,57–59,65]. In fact, a very early study that enrolled eight patients (four with cardiogenic shock and four with septicemia) reported a mean daily loss of 3.8 g/day of amino acids in septic patients and 7.4 g/day in patients with cardiogenic shock during CVVHF [57], while a more recent study in critically ill patients on CVVHDF reported a median amino acid loss of 13.4 g/day, ranging from 11.8 to 17.4 g/day, with ischemia being the most prevalent cause of AKI in 60% (6/10) of patients [65].

The optimal protein intake in critically ill patients with AKI is still unclear. It should be quantitatively sufficient to blunt skeletal muscle wasting, while providing the amino acids needed for the acute-phase response. Considering the increased loss of amino acids, patients on CRRT may require higher protein intakes [2,34]. Total nitrogen losses in a typical CRRT patient can reach up to 25 g/day [59,61], of which 10% is contributed by amino acid nitrogen loss [59], while the rest is likely to be derived from protein catabolism; this results in a

negative nitrogen balance. Nitrogen balance in these patients can be improved by increasing protein intake [61,62]. Protein intakes up to 2.5 g/kg/day, at least in nonrandomized studies, led to near positive or slightly positive nitrogen balance; however, urea generation rate was highly increased [61,62]. A positive nitrogen balance is associated with improved patient survival in AKI with critical illness, but improved survival is not a direct effect of increased protein intake [62]. Nowadays, a protein intake of at least 1.3 g/kg/day is recommended for critically ill patients [31]. Nonetheless, it seems rational to increase daily protein intake by 10–15 g in patients on CRRT to compensate for the loss of amino acids (AA). Whether a higher protein intake is safe and leads to improved outcome remains to be shown.

One important consideration regarding protein intake prescription is that it is frequently normalized using the body weight of patients. Taking into consideration that critically ill patients with AKI frequently have fluid overload, the determination of the reference body weight to be used for protein prescription is a delicate issue. In fact, different body weights will lead to different protein needs estimation, and despite technical difficulties that may occur during 24 hours urine and dialysis fluid collection, it is very important to calculate the protein catabolic rate in critically ill patients with AKI. Equations to guide clinical estimations are shown in Fig. 46.3.

Since standard enteral formulas contain low amounts of protein (40–60 g protein/L), more concentrated disease-specific (renal) formulas containing 70–80 g protein/L should be preferred, with no reported difference in the prevalence of diarrhea in comparison to standard formulas [66]; in some cases, parenteral supplementation

of amino acids is recommended to achieve protein intake goals [33,34,66].

## Lipids

Effluent samples in CRRT are mostly lipid free, with trace amounts of cholesterol and triglycerides detectable, and there is no gradient for lipids across the hemofilter to suggest membrane adsorption [67]. Lipid homeostasis is not significantly affected by CRRT. The only nonnutritional lipid sources to consider in the ICU are related to the use of sedatives such as propofol and clevidipine. The first provides 1.1 kcal/mL in a 1% solution, while the latter provides an extra 2 kcal/mL [68].

On the other hand, lipid oxidation rate is increased, and glucose oxidation rate is decreased during AKI [69,70]. Because fatty acids are considered a key energy substrate in critically ill patients [33,34,70,71], a complete diet, including all of the macronutrients, is important to avoid essential fatty acid deficiency and to provide the right amount of calories. Lipids should represent at least 30%–35% of total energy supply. In the case of parenteral nutrition, patients should receive 0.8–1.2 g/kg/day of lipid from lipid emulsions, or as a part of the commercially available all-in-one total nutrient admixtures. Lipids should be infused over 18–24 hours, and serum triglycerides should be monitored, stopping lipid administration when triglycerides exceed 400 mg/dL or 4 mmol/L. Even though the use of parenteral medium-chain triglycerides (MCT) may result theoretically in lower serum triglyceride because of their faster oxidation, pharmacokinetic studies failed to show any clear advantage in terms of plasma clearance of triglyceride from the mixed MCT/LCT (long-chain triglycerides) lipid formulas compared with LCT-only emulsions. However, in a short-term crossover study in patients with AKI that were on RRT and total parenteral nutrition, MCT/LCT emulsions produced lower serum triglyceride levels than the LCT-only-based formulas [29].

## Sodium and fluid balance

Because CRRT and PIRRT are RRT modalities running for prolonged periods of time, the net solute removal over time is higher than with intermittent hemodialysis, despite the lower rate of removal per hour. The most commonly adopted EN or parenteral nutrition (PN) formulas are generally hypotonic in sodium. Dialysis and replacement fluids are characterized by a sodium content of about 130–140 mmol/L, which generally provide the amount required to obtain an adequate balance. Hyponatremia in the course of

AKI is often a manifestation of fluid overload, primary due to oliguria and other clinical condition associated with positive fluid balance (e.g., congestive heart failure) or worsened by the administration of a large amount of hypotonic fluid volumes in course of resuscitation therapy. In this context, the decision to start CRRT may be based on the necessity of a renal support also in the absence of other strict dialysis indications, interpreting RRT as an adjunct to enhance kidney function and allowing the administration of nutrition and drugs with limited concerns about concurrent fluid accumulation. As previously mentioned, in the course of CRRT in the setting of RCA, the presence of hypernatremia could be attributable to an inappropriate combination of high concentrated citrate solutions and dialysis solution. In this sense, CRRT constantly controls the net fluid balance providing a gradual ultrafiltration throughout the entire treatment period. Through a slow salt and water removal, these dialysis modalities allow a steady modulation of fluid overload also in hemodynamically unstable patients. Moreover, in AKI patients on CRRT and severe fluid overload, it is advisable to deliver an ultrafiltration rate per hour that permits to administer all the necessary therapies (such as parenteral nutrition or antimicrobials) without a risk of fluid accumulation.

## Electrolytes and minerals

Although critically ill patients on CRRT are closely monitored with frequent laboratory tests, the onset of electrolytes abnormalities is not rare. In this sense a correct combination among the dialysate/replacement-fluid solutions, nutritional support, and micronutrients supplementation is strongly recommended to avoid laboratory and clinical complications.

## Hypokalemia

Hypokalemia is a common complication of CRRT, described in up to 20% of patients undergoing CRRT [72]. The risk of its presentation is directly proportional to the dialysis dose [73] and may be further augmented with the use of low-concentration potassium solutions (Table 46.2), inadequate nutritional composition, or comorbidities (e.g., diarrhea, metabolic alkalosis, and diuretic therapy). By choosing CRRT solutions with a potassium concentration 4 mmol/L the risk of hypokalemia can be minimized, but if the imbalance persists, intravenous external supplementation may be needed. Potassium solutions such as potassium chloride or phosphate can also be easily added to enteral nutrition.

## Hypo- and hypercalcemia

Alterations of calcium balance are quite uncommon among patients with AKI on CRRT, unless citrate is used as anticoagulant. As reported earlier, in course of RCA the infusion of calcium as chloride or gluconate is required to maintain ionized serum calcium levels within the normal range, especially when calcium-free dialysis fluids are used. Additionally, citrate accumulation, a potential complication of RCA with a reported incidence of 0%–12% [74], is associated with a fall in ionized calcium levels, as the result of impaired hepatic calcium release from the calcium–citrate complexes. A contemporary disproportionate rise of total systemic calcium concentration, represented by calcium complexed with citrate, may directly lead to an increase of the total-to-ionized calcium ratio (*calcium ratio*). In this setting the compromised citrate metabolism prevents bicarbonate generation, leading to negative buffer balance and metabolic acidosis. In the clinical practice a *calcium ratio* >2.5 is considered the critical threshold for an increased risk of impaired citrate metabolism [75]. In this regard, in clinical contexts at risk of citrate accumulation (e.g., severe liver failure and/or tissue hypoperfusion) monitoring of ionized calcium should be more frequent, and calcium ratio assessment carefully evaluated. With the exception of this peculiar condition, calcium abnormalities are routinely prevented by adjusting the calcium infusion.

## Hypophosphatemia

Hypophosphatemia is a common electrolyte disorder in course of CRRT, especially when high RRT doses are delivered [72] and standard solutions are adopted [76]. Indeed, every prolonged modality of RRT provides a large removal of phosphate with the effluent, leading to a significant total phosphorus clearance [77]. Hypophosphatemia is associated with worsening respiratory failure with an increased risk of prolonged weaning from mechanical ventilation, cardiac arrhythmias, prolonged hospitalization, and increased mortality risk [78]. Considering the negative impact of hypophosphatemia on global patients' outcome [79,80], phosphate depletion in course of CRRT should be avoided. In this regard, the adoption of phosphate-containing solution has been reported to represent a safe and effective strategy to prevent CRRT-related hypophosphatemia [81]. Nowadays, several phosphate-containing CRRT solutions are commercially available, and they are used as dialysis and/or and replacement fluids also in the setting of RCA (Table 46.2). A close monitoring of phosphorus levels is essential during CRRT and, particularly when phosphate-free fluids are used, additional supplementation may be required. Phosphorus supplementation can

be given via oral or intravenous route, infused intermittently, continuously, or added to parenteral nutrition. Especially in previously malnourished patients, additional phosphorus should be added to nutritional support, while caloric intake must be gradually increased to avoid the risk of refeeding syndrome [82]. This syndrome represents a possibly severe disorder in critically ill patients caused by the internal redistribution of phosphorus (and also potassium) into the intracellular compartment when calories are given to malnourished patients [83]. It seems to derive from the intracellular shift of phosphate mediated by insulin release and accelerated carbohydrate metabolism in response to the carbohydrate load. Finally, it is important to consider that the intravenous administration of phosphorus, if applied in the absence of a well-designed protocol and without strict monitoring, may increase the risk of further electrolyte abnormalities, such as hyperphosphatemia, hypocalcemia, and hypomagnesemia [84]. This approach is generally restricted to the cases of moderate-to-severe hypophosphatemia, or in the presence of symptoms.

## Hypomagnesemia

Hypomagnesemia is a common disorder in critically ill patients with a reported incidence of 60%–65% [85]. In addition to the most known causes (such as diarrhea, malabsorption syndrome, chronic use of proton pump inhibitors and diuretics, hypercalcemia, and volume expansion), particular attention has recently been addressed to magnesium removal during the course of CRRT. In particular, the onset and the exacerbation of hypomagnesemia in the course of CRRT have been demonstrated to be associated not only with the depurative mechanism of RRT (diffusion or convective clearance), but also with the amount of ionized magnesium chelated by citrate and lost into the effluent, under the form of magnesium–citrate complexes. The majority of previously available dialysis solutions were characterized by low magnesium concentration (0.5 mmol/L) to correct hypermagnesemia, which are not indicated during the course of RCA. Indeed, during RCA performed with a low-concentration citrate solution, the use of dialysis/replacement fluids with a high magnesium concentration (0.6; 0.75; 1 mmol/L) could be indicated to prevent RRT-related hypomagnesemia. Given the increased mortality associated with hypomagnesemia/magnesium depletion, if these alterations occur, an exogenous supplementation may be required. Magnesium administration can be given via oral or intravenous route, the latter approach being preferred in the case of severe and/or symptomatic hypomagnesemia. A continuous or slow intermittent extemporaneous intravenous infusion of 2–4 g of magnesium sulfate can be administered during the course of CRRT.

## Micronutrients

During critical illnesses, vitamins and trace elements may impact immunomodulation, wound healing and may have antioxidant properties [86,87]. Despite the fact that optimal dosing of micronutrients in critically ill patients is still a matter of debate, it appears quite clear that the start of CRRT in patients with AKI represents an additional variable negatively affecting serum micronutrient levels [88]. The depurative mechanisms on the basis of dialysis modalities along with a variable amount of hemofilter adsorption may increase the risk of vitamin and trace element deficiency, but dedicated and specific nutritional approaches are still lacking [89]. In patients on CRRT, a reduction in serum levels of vitamins C and E, zinc and selenium have been described, probably as a consequence of an increased utilization in critical illness [90,91] and loss secondary to CRRT. Specifically, daily losses in the effluent of about 68 mg of vitamin C, 0.3 mg of folate, and 4 mg of vitamin B1 (thiamine) have been reported [90,91]. The current suggestion is that the losses of selenium and other micronutrients in the effluent fluid should be replaced [92,93], and that these patients would need an additional amount beyond that provided by standard parenteral nutrition [91,94]. The optimal dose remains unknown, but a dosage of 100 mg/day has been suggested for vitamin C [95]. On the contrary, zinc, already present in some citrate solutions and replacement fluids, has been shown to be increased in serum after RRT start [63,91,96]. In conclusion, given the blood assay limitations and the lack of evidence of clinical advantages derived from micronutrients supplementation, no conclusive recommendations could be made.

## Conclusion

Continuous or prolonged RRTs provide an unparalleled precise extracellular volume and uremic control in critically ill patients with AKI and have greatly facilitated nutritional support in this clinical setting. The available evidence suggests that CRRT and SLED can be important sources of energy. To avoid overfeeding, IC should be applied for the determination of energy requirements, while the amount of extra calories provided through RRT should be taken into account when prescribing nutritional support. Amino acid losses can be significant with prolonged modalities of RRT. Special considerations exist for volume and electrolytes management, which will mainly depend on the protocols and solutions used. Nutritional requirements should be frequently reassessed, individualized, and carefully integrated with RRT in patients with AKI.

The adequacy and appropriateness of nutrition supplementation, especially protein intake, and the effect on protein energy–wasting risk and clinical outcomes, should be the target for future research in this field.

## Introduction

Patients with kidney disease are required to manage multiple nutritional and lifestyle changes and medical treatments to improve their health, including adherence to recommended diet and exercise routines, medications and health-monitoring activities, medical appointments, and in some cases, dialysis treatment. As kidney disease progresses, these demands increase and patients' motivation to meet them becomes more challenging. This diminished motivation may contribute to the patients' nonadherence and disengagement from their health-care providers. Helping patients with kidney disease implement and sustain necessary dietary plans, other healthy lifestyle activities, and medical regimens in collaboration with their nephrology team is critical for improving their treatment outcomes and quality of life. While treatment adherence for chronic illness involves many factors, such as patient demographics, treatment complexity and side effects, and availability of social and environmental supports [1], an important strategy to promote self-management is to activate the patients' motivation to manage their kidney disease [2].

This chapter describes an approach for enhancing patients' motivation for change, called motivational interviewing (MI) [3]. MI increasingly is being used in health-care settings to counsel patients with chronic diseases such as kidney disease [4,5]. The chapter reviews the basic principles and techniques of MI and

the evidence to support the use of MI for improving self-management among patients with kidney disease.

## What is motivational interviewing?

Miller and Rollnick offer a technical definition of MI as "a collaborative, goal-oriented style of communication with particular attention to the language of change. It is designed to strength personal motivation for the commitment to a specific goal by eliciting and exploring the person's own reasons for change within an atmosphere of acceptance and compassion" (p. 29) [3]. The approach is grounded in humanistic psychology, especially the work of Rogers [6], in that it employs a very empathic, non-judgmental style of interacting with patients and presumes that the potential for change lies within everyone. MI is distinct from nondirective approaches; however, in that providers intentionally attend to and selectively reinforce patients' motives that support change [3,7,8]. The elements of (1) partnering with patients, (2) non-judgmentally accepting their stance, (3) showing compassion, and (4) evoking the patients' own arguments for change collectively represent the spirit of MI. Over the course of the interview, providers help patients identify these change-oriented motives, elaborate upon them, and resolve ambivalence about change. If successful, patients become more likely to commit to changing their behaviors and initiating a change plan.

Skilled health-care providers try to match their use of MI strategies to the patients' level of motivation. For example, a skilled provider can recognize when patients are motivated and ready to make changes and will move quickly to set a goal with patients. This is because extensive exploration of their motives for making a change might frustrate patients who are ready to move forward. In contrast, attempting to develop change plans with patients who are not yet committed to change will likely put patients in a position in which they might assert in words or in actions how they are not yet ready. This latter interaction illustrates how motives to change (called "change talk") and motives to stay the same (called "sustain talk") can be thought of as opposite sides of the same coin, meaning that if providers give insufficient attention to addressing important issues that impede change, patients are likely to raise these issues again during the interview [3]. Often providers expect patients who initially argue against change to have some intrinsic motivation for change within them. It is the responsibility of providers to look for opportunities to draw it out.

MI is best construed as a "conversation about change" (p. 12) that is designed to strengthen personal motivation and commitment to change [3]. In this regard, MI often is discussed within the context of the Stages of Change model by Prochaska and DiClemente [9]. The Stages of Change model posits that behavior change occurs sequentially across recurring stages. The earlier stages include precontemplation (patients are unaware or do not believe that there is a problem or need to change it), contemplation (patients are ambivalent about recognizing a problem and shy away from changing it), and preparation (patients are ready to work toward behavior change in the near future and develop a plan for change). The later stages include action (patients consistently make specific changes) and maintenance (patients work to maintain and sustain long-lasting change). Tailoring treatment strategies to achieve stage-related tasks is a hallmark of this model (e.g., conducting a cost-benefit analysis for someone contemplating change).

MI naturally fits into the Stage of Change model in that it can be used to help move patients from one stage to another, especially in the early stages of the model [10]. Patient-centered counseling skills may build rapport and engage patients who are less motivated to change. Eliciting additional change talk might lead ambivalent individuals to conclude it is relatively worth it for them to change rather than to not address areas critical to their health and quality of life. Working with patients to identify steps they can take might help them feel more prepared to initiate a change plan. In later stages, MI strategies are useful for attending to wavering motivation as patients

take action or try to maintain changes in stressful situations. Finally, the Stages of Change model illustrates how MI integrates well with other treatment approaches that are more action-oriented. For example, MI might be used to engage patients in kidney disease education and skill-building activities (e.g., meeting with a dietitian to learn how to consume the right balance of protein) or in other treatments for comorbid conditions (e.g., cognitive behavioral therapy for depression) [11].

MI emerged out of early efforts to establish brief interventions for alcohol problems [12]. These interventions shared a harm reduction approach in that they aimed to help patients move toward reduced drinking to lower risks rather than to automatically advocate for total abstinence as the only acceptable goal. Common components of these brief interventions, as represented in a FRAMES acronym, were Feedback, emphasis on personal Responsibility, Advice, a Menu of options, an Empathic counseling style, and support for Self-efficacy. With FRAMES as a guidepost, William Miller and his colleagues developed the "Drinker's Check-up" in which patients received feedback about their drinking relative to population or clinical norms and then explored what it might suggest about their drinking and motivation for reducing or stopping it. Early studies found the Drinker's Check-up to be quite effective [12]. Given this success, MI with personalized assessment feedback then became adapted into a more structured and manualized format and termed motivational enhancement therapy or MET [13].

As applied to the management of kidney disease, the harm reduction stance of MI implies that the aim of MI is to help patients prepare themselves to make changes in any behaviors that might positively impact their kidney disease. Determining what areas matter most to them (e.g., diet, exercise, and medication), which areas they believe they can change (e.g., limiting fluid intake, increasing activity level), and what goal to achieve (e.g., walking 15 min/day) is more important than pushing them to commit to something they may not want to or feel able to achieve, even if full adherence would have obviously better health outcomes.

Implied in the previous discussion is that MI is behaviorally specific and has direction. This means that providers need to be clear about what it is that they are trying to motivate patients to do or to change. Motivation for change in one area does not guarantee motivation for change in another (e.g., a patient may commit to taking a phosphorus binder but not agree to substantially limit foods high in sodium). Each behavior may require a separate motivational enhancement process. MI also requires that providers take a stance about the preferred direction for change. For many behaviors related to kidney disease, this decision is relatively clear

in that most patients would agree that it is ethically sound to enhance motivation for changes that decrease morbidity and mortality, such as blood glucose control or smoking cessation. However, some behavioral issues involved in kidney disease care do not have a clear change direction. For example, decisions about whether to start end-stage renal disease therapy with peritoneal dialysis or hemodialysis or proceed with a preemptive kidney transplant likely would require a nondirective approach in which providers suspend their own values or goals and assume a position of "equipoise" (i.e., indifference or no clear attachment to a position or recommendation). In these situations a patient-centered counseling approach, devoid of evocation, would allow patients to explore their ambivalence without intentional provider influence.

### **What is not motivational interviewing?**

For clarification purposes, it is helpful to consider what MI is not [7]. As noted earlier, MI is not based on the Stages of Change model, though it is complementary to it. Stages of Change is more of a comprehensive way of thinking about how patients change, whereas MI is a clinical method that helps patients prepare for change. Likewise, MI is not cognitive behavioral therapy. The latter approach supplies patients with education and coping skill development and encourages the repeated practicing of these skills to better manage their problems. MI is fundamentally humanistic, not behavioral, in origin in that it elicits the patients' motivations for change rather than putting in place what is missing (knowledge and skills). MI also is not a way of manipulating others or making them change when they do not want to. Behavior change in MI is born out of a person's intrinsic motivations. Health-care providers can only call forth motivations that already exist within patients; they cannot impose the concerns or wishes of others when an individual does not see these issues in his/her best interest. Finally, MI does not require that providers conduct a decisional balance or give personalized feedback. These are techniques that often are helpful for eliciting change talk, but they are not essential to the conduct of MI, and they often are used in other treatment approaches. In this regard, MI is not a series of techniques but rather a way of being with patients in which guiding attitudes and practices orient the patient toward change.

### **Four motivational interviewing processes**

There are four processes that comprise MI: (1) engaging; (2) focusing; (3) evoking; and (4) planning,

with each process often overlapping with each other. Miller and Rollnick define engaging as, "the process of establishing a mutually trusting and respectful helping relationship" (p. 40) [3]. In the engaging process the provider seeks to establish a partnership by facilitating the patient's story using fundamental MI strategies (e.g., open questions, reflections). In doing so the patient can share his or her perspective, and rapport is cultivated within the dyad.

Focusing is "an ongoing process of seeking and maintaining direction" (p. 94) [3] by identifying areas for exploration in treatment. These areas are determined through a combination of the patient (e.g., focusing on improving dietary changes), the setting (e.g., dialysis clinic), and the clinical expertise of the provider (e.g., improve anhedonia that is interfering with treatment engagement). Listing agenda items on paper and helping the patient prioritize them is a hallmark strategy used to focus the interview on specific behavior change targets (see the "Other useful strategies" section).

Evoking is the third process in which the provider tunes into the patient's language that favors change (change talk) and applies strategies to generate change talk if not readily offered by the patient. There are several ways for providers to evoke change talk as outlined in Miller and Rollnick [3], including but not limited to (1) eliciting what the patient knows, providing information, and eliciting the patient's reactions to the information; (2) using open questions and reflections to further change-oriented discourse; (3) assessing and exploring the patient's importance and confidence related to making changes using a numeric scale; and (4) engaging the patient in a decisional balance activity to explore the benefits of change and the costs of not changing. These strategies can be used in traditionally briefer medical encounters and applied by members of the patient's interdisciplinary care team, making them ideal for multispecialty settings.

Finally, the last process is planning, where the patient identifies a self-prescriptive behavior change goal. It is described as "developing a specific change plan that the person is willing to implement" [3]. Often, a patient is ready to transition to planning when the frequency of change talk has increased and indicates that the patient is ready to prepare for change. This includes expressing commitment to change, activation or readiness around change (e.g., pondering potential options to facilitate change), and taking initial steps to initiate behavior change. During this stage, providers assist patients in setting the change plan that includes anticipating obstacles, identifying supportive others, and reaffirming their commitment to change. If the patient voices ambivalence during the planning process, providers explore it rather than pushing to

complete the plan when the patient has backtracked motivationally.

## Strategies

While MI is a style of being with others rather than merely an application of techniques, MI incorporates several strategies that operationalize how providers use MI [3]. These strategies include (1) those that are fundamental to the approach and used throughout the MI processes, such as open questions, affirmations, reflections, and summaries (known as OARS) and (2) direct methods for evoking change talk. The continuous interplay of fundamental patient-centered strategies and direct methods to elicit and reinforce change talk is essential to conducted MI proficiently. In addition, other useful strategies can help patients prioritize behavior change issues and allow for a collaborative exchange information between patients and providers.

### Fundamental strategies: open questions, affirmations, reflections, and summaries

Fundamental strategies are a mainstay of MI in that they help providers understand the patients' perspective, convey empathy, and build a positive relationship with their patients. As the conversation unfolds, health-care providers attend to the balance of statements made by patients that support or thwart behavior change (i.e., change vs sustain talk) to gauge the patients' level of motivation and adjust their use of MI techniques accordingly. Open questions encourage patients to talk more and may be used to strategically draw out motivations for change (e.g., "What would be good about quitting smoking?"). They stand in contrast to closed questions, in which providers seek specific information (e.g., demographics, history, and symptoms), often with questions that can be answered with a "yes" or a "no" response. For example, a patient's positive response to the closed-ended question, "Have you been sticking with the diet we discussed last time?" would provide some useful information. However, he or she would not have fully elaborated on adherence to various aspects of the dietary plan, which an open question (e.g., "What parts of your plan have you been able to stick with since we last met?") might have elicited.

Affirmations (i.e., acknowledgment of a person's strengths, attitudes, and efforts that promote behavior change) build collaboration between providers and patients and promote self-efficacy. Sometimes this entails reframing a behavior in a manner that helps patients see it in a more positive light. For example, a

provider who has a patient who becomes dismayed by his series of self-monitored high blood glucose readings might say, "You're keeping a close eye on your blood sugar to get it under better control."

MI also relies heavily on the skilled use of reflective listening in which providers restate or paraphrase their understanding of what patients have said to express empathy, as well as to bring attention to ambivalence, highlight change talk, and explore and lessen language that supports the status quo. In MI, reflections are "simple" when a provider essentially repeats what the patient has said and "complex" when the provider articulates new meaning implied by the patient's original statements. Complex reflections demonstrate a deeper understanding of the patient's experiences. As an example, a provider asks a patient with kidney disease, "How have things been going with dialysis?" The patient responds by saying, "What difference does it make?" A provider could use a simple reflection to encourage more discussion about the patient's expressed skepticism ("You're not sure dialysis makes a difference"). A complex reflection would capture the patient's implied demoralization and show more empathy ("You seem pretty discouraged").

Summaries provide opportunities for providers to demonstrate fuller understanding of their patients' experiences and help them consider the bigger picture of their motivations for change. Summaries also allow providers to collect multiple change talk statements as a strategy to enhance motivation, link discrepant statements that capture ambivalence, and shift focus to other behavioral areas (e.g., move from discussing medication adherence to exercise). The following is a dialog that ends in a summary statement. Use of fundamental strategies is italicized.

**Provider:** How have you been doing? (*open question*)

**Patient:** Not too well actually. I have been having several annoying problems.

**Provider:** You sound frustrated. (*complex reflection*)

**Patient:** I am really frustrated. [pause] Sometimes I feel like not even bothering with this treatment.

**Provider:** It is a lot to handle. (*complex reflection*) Tell me about the problems you've been having. (*open question/request*)

**Patient:** Well first of all, I've been having a lot of muscle cramps. They are mostly in my legs and they are quite painful. I get them especially when I sit around for awhile and sometimes when I am sleeping; they wake me up and I have to walk them off. The other thing is itching. It drives me crazy. I am scratching myself all the time. Between the cramps and the itching, I feel like I am

being attacked from inside and outside. Is there anything we can do about it?

**Provider:** There are several things that are possible. Muscle cramps and itching are common for people with kidney disease. However, the causes may differ among people. We will have to talk a little more about it. I also will want to check your blood level of phosphorus and a hormone called PTH that can lead to itchy skin. (*patient-centered feedback*)

**Patient:** Alright. There is one more thing. I also feel tired most of the time. Sometimes I wonder if I am getting depressed.

**Provider:** You are not sure if you are tired because of the kidney disease or if it is due to being depressed over having to deal with the disease. (*complex reflection*)

**Patient:** Yeah. Sometimes it is hard to make sense of things. I guess I am hoping that you can help me figure things out.

**Provider:** It is confusing, and I certainly hope we can work together to figure it out. (*simple reflection that builds collaboration*) I really appreciate how you're being open about what you're experiencing (*affirmation*).

**Patient:** Well, I really don't have anyone to talk to about what I am going through. Sometimes I want to forget all about it and give up. Other times, I try to be strong and positive and do everything I can to delay having dialysis. It's such a battle – one that I fear I might be losing.

**Provider:** And it might feel that way because there is a lot on the field. You've been having painful leg cramps, lots of itchiness, and you are beginning to feel depressed by it all. Nonetheless, you're still trying to work with us and find ways to address these problems. You haven't given up (*summary; affirmation*).

## Direct methods to evoke change talk

Direct methods for evoking change talk hinge on the capacity of health-care providers to recognize how patients talk about change [3,8,14]. Change talk is embodied in the acronym DARN-CAT (see Table 47.1). DARN (desire, ability, reasons, and need) is sometimes referred to as preparatory language in that these statements motivational factors prepare patients to commit to change [14]. Desire statements indicate a clear wish for change (“I don’t want my kidney disease to get worse”). Ability statements indicate patients’ beliefs that they can change, given their skills and available

TABLE 47.1 Change talk categories: DARN-CAT [33].

Category	Definition
Desire	Statements that indicate a clear wish for change
Ability	Statements that indicate patients’ beliefs that they can change
Reason	Statements that note the benefits of change and the costs of not changing
Need	Statements that underscore how the problem behavior interferes with important areas of a patient’s life and how changing the behavior would likely improve matters
Commitment	Statements that convey a patient’s intention to change
Activation	Statements that indicate how patients are getting ready to change
Taking steps	Initial demonstration of behaviors that would support change

resources (“I used to swim, and there is a YMCA in my town that I could go to”). Reason statements note the benefits of change and the costs of not changing (“I will feel better” or “If I stop drinking soda, I might get my blood sugar under better control”). Need statements underscore how the problem behavior interferes with important areas of an individual’s life and how changing the behavior would likely improve matters (“I don’t want to be the next person in my family to die from kidney disease” or “I certainly want to teach my kids how to live a healthy life to prevent this from happening to them”).

CAT (commitment, activation, taking steps) represents statements that suggest patients are mobilizing themselves for change. Commitment statements convey the stated intention to change (“My quit date will be this Thursday”). Activation statements indicate how patients are getting ready to change (“I am going to fill the prescription at the pharmacy right after I leave here”). Statements about taking steps to change are the strongest demonstration of commitment in that the patients have put their words into action and are reporting these early efforts to the provider (“Instead of going out to drink after work, I went to the gym and exercised”).

During the interview, providers identify the extent to which patients express motivation in each of these areas, use their fundamental skills to support and develop patients’ change talk and have them elaborate further, and in a goal-oriented fashion, directly attempt to evoke motivation for change. MI offers multiple techniques for these purposes. Some options are described next:

1. Evocative questions—directly asking open questions to elicit change talk (e.g., “In what ways do you

- think you can better manage your kidney disease?" [evoking ability to change] "How would things be better for you if you followed the recommended diet?" [evoking reasons to change]).
2. Readiness rulers—asking patients to rate themselves from 0 to 10 about the importance of and their confidence in changing a specific behavior related to their kidney disease and following up with evocative questions designed to elicit change talk (e.g., "How come you said a 5 rather than a 0?" "What would it take for you to go from a 5 to a 6?").
  3. Looking forward—asking patients open questions to look to the future at some time interval (e.g., 5 years from now) and consider where their lives might be headed with and without healthy lifestyle changes (attempting to reveal potential reasons or need to change to enhance the importance of change).
  4. Exploring goals and values—inquiring about what matters most to patients (e.g., being a good parent or available grandparent, independence) through reflections and open questions and how the targeted behavior fits with these goals or values (e.g., "The thought of being tethered to a dialysis machine is unacceptable to you. How would being more physically active affect your level of independence?").
  5. Past successes—exploring past periods when patients were successful in some areas and how they might import these experiences into their current circumstances ("It's great that you were able to stay on top of your diet by tracking the foods you ate; keeping it up for several years is impressive. What helped you be successful then? How can those strategies work for you again?").

## Other useful strategies

Kidney disease management typically requires simultaneous attention to several behavioral issues (e.g., diet, exercise, medication adherence, adherence to the dialysis treatment regimen, blood glucose control, blood pressure control, phosphorus control, smoking cessation, comorbid depression, or anxiety), and this reality often is overwhelming to patients and their health-care providers during any one appointment where time is limited. Providers can use a simple agenda setting chart in which they record the pertinent behavior change issues on paper and have patients indicate which of them they want to discuss during the interview [14]. It is important that these priorities be put in the context of the concerns the provider has about the patient's medical status. For example, if a patient is poorly compliant with the dialysis treatment regimen but wants to focus on his minimally elevated phosphorus level, the

provider will need to organize the conversation appropriately to share concerns about treatment adherence while simultaneously addressing the patient's priorities.

Education, advice-giving, and direction are commonplace in the health-care settings, particularly because providers' often have a natural tendency to try to fix patients' problems (referred to as the "righting reflex") [3]. When patients have not solicited professional input, however, they may not be receptive to it. Instead, providers ask permission to provide information or advice and employ an elicit—provide—elicit (or ask—tell—ask) technique in which providers (1) elicit from patients what they know about the topic being discussed, (2) provide information as needed, and (3) elicit patients' reactions to the shared information [4]. For example, a provider may wish to recommend that a patient meets with a dietitian. Instead of providing the recommendation in an unsolicited manner, the provider would first ask the patient about his or her past experiences with dietitians and then, with permission, talk about how a dietitian might be helpful to the patient and conclude by getting the patient's reaction. This technique promotes collaboration and reduces the chance that patients experience their providers as lecturing or telling them what to do.

The following conversation between a provider and his patient demonstrates the use of several strategies (italicized) described earlier:

**Provider:** When we last met, we reviewed some recommended changes to your diet because your blood pressure was elevated. What is your understanding of your blood pressure right now? (*Elicit*)

**Patient:** The nurse said that it was 155 over 95, which is better than what it had been.

**Provider:** Those numbers are correct! We would like to see that top number safely below 130 which means your blood pressure today is on the high side. (*Provide*) Last time we talked about reducing salt in your food. How did it go?

**Patient:** Not that well. I tried to cut back on salt, but I don't like how things taste if they aren't seasoned.

**Provider:** Even though you like the taste of salt, you still tried to reduce how much you use (*Affirmation*). How come? (*evocative question*)

**Patient:** I was worried about my health, and I want to see my granddaughter graduate medical school. You said my blood pressure was high and that it increased my risk for all kinds of problems, especially heart problems. Did you say my blood pressure is still high?

- Provider:** Yes. It is 155 over 95, which is higher than our target needed to keep you safe from other health risks like cardiovascular problems, like heart attack or stroke. (*Provide*) You mentioned feeling an urgency to stay healthy so you can celebrate your granddaughter's achievements. What are your thoughts about how your diet may be impacting your blood pressure? (*Elicit*)
- Patient:** It's just so hard to eat foods that taste bland and even more difficult figuring out what I can eat at a restaurant. I'm really upset with myself that I can't seem to control what I put in my body.
- Provider:** And you fear that if you don't begin to find ways to reduce how much salt you eat, you may even risk not being able to attend your granddaughter's graduation. (*exploring goals and values, looking forward*)
- Patient:** That's the worst of it. My granddaughter is working so hard to become a doctor, and I'm having trouble doing what the doctors tell me to do.
- Provider:** You'd like to better manage your health for yourself and your granddaughter. Finding ways to cut back on salt is very important to you. (*exploring goals and values*)
- Patient:** Yes. I just keep running into the same problems. Food just doesn't taste good without salt.
- Provider:** So how can you make food taste better without eating too much salt? (*evocative question*)
- Patient:** Well, I could cook with more spices and use more fresh food rather than canned foods or frozen dinners.
- Provider:** You have some good ideas (*affirmation*). Can I share with you another idea that some people have found helpful? (*asking permission*)
- Patient:** Sure.
- Provider:** What are your thoughts about meeting with the dietitian to help you discuss other ways of sprucing up your meals? (*evocative question*)
- Patient:** Sure. I thought I could just do it on my own, but I think I need some help learning how to cook in a different way.

Use of a decisional balance activity (i.e., exploring the costs and benefits of changing and not changing) is common in MI [3]. This activity provides a structured method for understanding the basis of a patient's ambivalence in that the benefits of change ("I'll delay the need for dialysis for many years") and the costs of

not changing ("If I don't change how I eat and exercise, a heart attack may kill me before my kidney disease does") provide reasons to change, whereas the benefits of not changing ("A person has got to have some pleasure") and the costs of changing ("Healthy food is expensive") provide reasons to remain the same. By strategically eliciting more reasons for change and, to the extent possible, resolving reasons to remain the same (e.g., identify some healthy foods that taste good and are affordable), a provider might help the patient tip the balance toward change. However, it is recommended that the use of decisional balances be applied with caution. In a 2013 study, Miller and Rose found that the use of decisional balances with clients who were ambivalent ultimately decreased the decision to change [15]. They suggest that the use of decisional balances be reserved for clients who have already decided to change, which can strengthen their commitment. They recommended other evocation strategies, like some of the direct methods described earlier, may be more effective in resolving ambivalence.

Another important skill is how to gauge patients' readiness to change and transition from the evoking to planning for change. Providers typically recapitulate what patients have said, especially those statements that suggest how they are now ready to change. Following this summary, providers then pose a key question to solidify commitment to change ("What's your next step?" or "From what you've told me, how do you want to proceed?"). Miller and Rollnick have used the analogy of a person as a skier standing at the summit (assisted up the mountain by the provider) [3]. The key question provides a supportive nudge that helps the person go down the mountain.

Change planning is a strategy that providers use to negotiate a plan with patients about how they will change their behavior [3]. Critical to this process is maintaining a patient-centered stance in which the plan is derived by the patient, with the assistance of the provider, rather than the provider becoming prescriptive at this point. Providers ask patients to set their targeted behavior change goal ("I am going to monitor my blood sugar once a day"), describe steps they will take to change ("I will test it in the morning before I eat my breakfast"; "I will record my level each day on my monitoring form"), identify who might support them and how ("I am going to ask my wife to review my sugar levels at the end of each week"), anticipate obstacles ("I travel once in awhile and need a way to not forget to take my glucometer with me"), and reaffirm their commitment to the plan. If during the process of mobilizing their commitment, patients become uncertain again (the cold-feet phenomenon), the provider reflects this ambivalence rather than trying to press through it and provides another opportunity

to revisit the plan in the current meeting or at another time. Being in a hurry to complete the plan when patients are not ready is a common trap into which providers fall.

### **Handling sustain talk and discord**

Previously known as “resistance,” sustain talk refers to a patient’s statements about what maintains the target behavior, whereas discord refers to challenges within the interpersonal dynamic between the patient and the provider [3]. This revision in language was made in response to concerns that the word “resistance” insinuated a sense of patient-driven opposition or pathology and excluded the interpersonal dynamic between the provider and patient that may be contributing to the disconnect [3].

Sustain talk conveys the patient’s intent to make no changes to behavior. The patient may offer reasons for maintaining the behaviors (“Eating a lot relaxes me”) or the difficulties of trying to change them (“I can’t resist the urge to smoke”). Sustain talk in this context informs providers about dilemmas faced by individuals, thereby providing opportunities for addressing obstacles to change. Some strategies for skillfully handling sustain talk include (1) simply reflecting the sustain talk to show empathy and better understand the issue (“You don’t believe you should have to make any further changes in the way you eat when you feel you have made big changes elsewhere” in response to a patient who says, “I already take the meds, cut back on soda, and started walking after work. I don’t want to change my diet anymore”); (2) amplified reflections to determine the degree of commitment to a discordant statement (“Your wife has no basis to be concerned about your weight” in response to a person who complains how his wife pesters him about his obesity); (3) double-sided reflections to pair the sustain talk with other things said that favor change, thereby introducing some ambivalence back into the conversation (“You feel like stopping the medication now that you have changed your diet and exercise, and you worry that if you do, you might develop hypertension again”); and (4) emphasizing personal choice and control to assure the patients that it is they who determine what they will do, not others (“Dialysis is not easy, but it is manageable and you have a few options about how to do it. We will work with you to determine what the best way is to go about getting dialysis, and ultimately it is your decision”).

Miller and Rollnick describe discord as “smoke alarms” or “a change in the air” to alert providers that there has been a shift in the working alliance [3]. They describe patient behaviors such as defending

themselves through external blaming or justification, squaring off with a provider (i.e., “You don’t care, don’t know, have no idea etc.”), interrupting, and disengaging from the conversation as examples of discord. In using MI, a provider avoids adopting a confrontational, authoritative, warning, or threatening tone (all inconsistent with MI), which might cause the patient to become even less engaged in treatment [14]. These behaviors can originate from the patient, well before the visit begins, or discord can arise during the visit (and often unintentionally provoked by the provider). Provider behaviors such as using labeling language (e.g., alcoholic, diabetic), disagreement over which behaviors to focus on, overcorrection of patient’s beliefs and perspectives about change, and prematurely pushing toward planning can generate discord within the interaction. Strategies for navigating discord include affirming patient’s strengths and effort which can attenuate defensiveness. Additionally, shifting the focus on the conversation away from the activating topic can bring patient and provider back in sync on their shared goals for treatment. For example, a patient stating, “You don’t think I’m trying hard enough, do you?” in response to a provider assessing importance. In response, the provider might say, “When I asked about how important you feel it is to make changes to your diet, it felt like a judgment. My goal is to learn more about the things that are important to you versus me falling into a trap of imposing my values onto you. Perhaps we can talk about all of the ways that you’ve been working hard to make changes to your diet.” Alternatively, simply apologizing, “I’m very sorry. I didn’t mean to sound judgmental” can help mend fractured rapport when experiencing discord with a patient.

Successfully managing kidney disease is difficult for several reasons. As described earlier, patients must continuously manage numerous medical treatments (scheduled appointments, dialysis regimens, prescribed medications, and health-monitoring activities) and address several nutritional and other lifestyle changes to treat their kidney disease and associated comorbidities. These demands on patients increase as their kidney disease progresses, and their motivation to meet them typically fluctuates over time. Providers who use MI with patients understand that sustain talk is more of a reflection of what makes change hard for them rather than as a refusal to change or mere ignorance. The former perspective promotes empathic and supportive provider–patient interactions. The latter one might lead providers to label patients as “unmotivated” and confront, warn, or lecture them, thereby, risking putting patients in a position of defending themselves by arguing for their status quo behaviors [16].

The next dialog demonstrates the use of MI strategies for handling sustain talk and discord (italicized in text) with a dialysis-dependent patient who needs to lose weight to become eligible for a kidney transplant.

**Provider:** I'd like to talk with you about your weight if that's okay with you? (*emphasizing personal choice and control*)

**Patient:** Sure, but I already know what you are going to say.

**Provider:** You're concerned I'm going to give you a lecture rather than try to understand what makes losing weight difficult for you. (*reflection*)

**Patient:** Well I know what I must do and I've tried it all before. It's just so hard now with all these adjustments to my diet, and I'm too tired to move around like I used to.

**Provider:** So having tried everything and being so exhausted, you feel like there is nothing you can do about your weight. (*amplified reflection*)

**Patient:** That's not what I said. I just don't feel I can do it on my own. You're putting words in my mouth.

**Provider:** My apologies. I missed the mark on describing your thoughts about your diet. (*apologizing*) Perhaps we can explore what would help you be successful with making changes to your diet. (*shifting focus*)

**Patient:** It's like I need a coach or something to help me, to point me in the right direction and keep me going. I'm worried about it because I want to get the kidney transplant.

**Provider:** So your diet is somewhat complicated and tiredness gets in your way. On the other hand, you want to go to the kidney transplant evaluation knowing you meet the criteria, which requires that you lose weight to be listed. You feel you might be able to lose weight if you had someone to coach you along the way. (*double-sided reflection*)

**Patient:** Yeah. Could I get someone like that to help me out?

**Provider:** Sure. There are a few options. You could meet with the dietitian regularly, and she can serve as a coach. We also have a weight control program right here, that I can refer you to. Program counselors work closely with you to help you lose weight. Another option is for you to go to a program in the community, like Weight Watchers or others, if you don't want to come here. If these approaches don't work, then we can consider medication or surgical options, but it would be best to first try to improve your eating and exercising, especially since you will need

to improve these areas anyway to increase the chance that kidney transplantation succeeds. What do you think? (*emphasizing personal choice and control*)

**Patient:** What's the program like here?

## Empirical support

Several systematic reviews and meta-analyses [17–20] have examined the large body of MI research to determine *if MI works* across a wide range of problem areas (e.g., alcohol, tobacco, illicit drugs, diet/exercise, treatment adherence/engagement, blood pressure, weight loss, smoking and substance use, and physical activity). A recent systematic review of 104 narrative reviews and metaanalyses of MI treatment outcome studies suggests that the evidence for beneficial effects of MI is strongest for reducing binge drinking, frequency and quantity of alcohol consumption, substance abuse in people with dependency or addiction, and increasing physical activity participation [21].

Along with questions about the effectiveness of MI come concerns about the speed in which effects are observed. Arguably the busiest setting, a meta-analysis examining the application of MI in primary care, found MI to be useful in promoting health-related behavior change in as few as one session [21]. Additionally, Lundahl and colleagues examined 119 studies and found MI to successfully produce behavior change, but in less time, compared to other interventions [18]. MI also significantly increased patients' treatment engagement, with effects being durable, lasting up to 1 year.

The effectiveness of MI delivery systems outside of face-to-face interactions has also demonstrated effectiveness. Previous research suggests that face-to-face modalities of MI-based interventions are more effective than those delivered by phone [22]; however, in recent years, more studies have emerged regarding the acceptability and feasibility of computer and web-based platforms [23,24]. There has been some success with computer-based MI interventions for adults related to initiating substance use treatment after a 2-month follow-up [25], and also related to weekly minutes of moderate and vigorous physical activity [26]. Randomized trials related to postpartum substance use have demonstrated efficacy and acceptability of electronic "screening, brief intervention and referral to treatment" (SBIRT) models that utilize MI [27,28]. Other studies have also found equivalence between electronic SBIRT and clinician-delivered SBIRT models where both included the same amount of MI principles [29].

MI is also effective for changing health behaviors across the developmental lifespan. A 2014 meta-analysis conducted focused on adolescent health behaviors

(such as risky sexual behavior, physical activity, and diet) demonstrated short-term post-intervention effects that were maintained, on average, 8 months after the intervention concluded [30]. Among middle-aged and older adults, MI has demonstrated effectiveness in reducing episodes of unprotected sex following a four-session, telephone-delivered MI intervention [31]. Health promotion and disease prevention efforts among older adults are also benefitted by MI, particularly with increasing fruit and vegetable consumption, physical activity, glycemic control [32].

Studies examining *how MI works* have supported the underlying theory of MI. Miller and Rose provide a helpful summary of this literature [8]. In brief, these studies have shown that providers who adhered to MI, in contrast to those who did not, were more likely to have patients who became more motivated to change and, in turn, had improved treatment outcomes (e.g., reducing drinking, meeting dietary goals, increasing activity level) [33–42]. A 2018 meta-analysis of MI process studies found that when providers use a higher proportion of MI consistent strategies, their actions are likely to result in patients who use proportionally more change than sustain talk [43]. Higher proportion change talk, in turn, was related to reductions in risk behaviors at follow-up. MI inconsistent behaviors were correlated with more sustain talk. Independent of other effects, more sustain talk was associated with worse outcomes. This meta-analysis suggests that MI works well when providers perform it well (i.e., with adherence to its principles and strategies). Getting sufficient training and supervision to learn MI is imperative (see the “Learning motivational interviewing” section).

Furthermore, nuances in the frequency and movement in change talk (i.e., toward change, away from change) appear to impact clinical outcomes. One study found that ending treatment sessions when in a “toward change” position resulted in less alcohol consumption (13 drinks) per week when compared to sessions that ended with “away from change” [44]. Most notably, Glynn and Moyers [45] employed an applied behavior analysis design to intentionally increase or decrease the amount of change talk, with success. This finding suggested that even within the absence of other MI skills, evoking change talk specifically may be a critical strategy to any behavior change intervention [45].

### **Applications in kidney disease management**

MI has been successfully adapted for use in health-care settings to manage chronic disease, including diabetes. Several studies have shown that MI can be an effective method of working with teenagers and adults

with diabetes, producing improvements in glycemic control, psychological well-being, and quality of life [46–48]. MI also has moderate-to-strong effect sizes for a variety of health-related behaviors involved in the management of chronic kidney disease (CKD), such as healthier eating [49–52], increased physical activity [49,53,54], improved blood pressure control, weight loss [49], better medication adherence [55], and better glucose self-monitoring [56]. A 2010 systematic review of 87 studies of behavior change strategies used in nutrition counseling demonstrated that MI was a highly effective counseling strategy [57].

Additionally, the nephrology literature has reported on applications of MI for kidney disease management. Fisher and colleagues [58] described efforts to improve fluid management among five hemodialysis adult patients. Their intervention combined MI with cognitive behavioral therapy for up to 12 sessions and found that three of the five patients reduced both the mean interdialytic weight gain and the frequency in which they gained more than 3% of their dry weight. van Vilsteren et al. [59] randomly assigned 96 sedentary hemodialysis patients to a low-to-moderate 12-week renal rehabilitation exercise program with or without the addition of four MI sessions to improve exercise adherence. They showed that relative to the control condition, the addition of MI yielded significant increases in reaction time, lower extremity muscle strength, increased exercise resulting in improved  $Kt/V$ , and three quality-of-life components.

MI can be utilized by the clinical team, especially MI-trained nurses, to help empower patients to be engaged in the self-management of their care [60,61]. A randomized trial of 793 patients with kidney disease in nine Dutch hospitals examined the use of an MI-trained nurse in coaching patients with kidney disease around adherence with self-management [62]. They looked at cardiovascular morbidity and mortality, all-cause mortality, renal function, vascular damage markers, and quality of life over the course of 5 years and found that supplementing care with an MI intervention slowed renal death and improved glomerular filtration rate outcomes. Cardiovascular outcomes, however, were not improved, which suggests a differential benefit related to kidney functioning.

MI has also been studied as it relates to adherence in managing kidney disease. A 2011 study examined the use of staff-delivered MI in an outpatient hemodialysis setting. They found improvements in dialysis attendance (less skipped visits) and length of treatment sessions (fewer prematurely shortened sessions), in addition to improved biomarker outcomes (i.e., phosphorous and albumin) [63]. In a 2014 study in Spain, six monthly treatment sessions which included both MI and cognitive behavioral skill training focused on

self-management of CKD resulted in higher self-reported levels of treatment adherence, reductions in depression and anxiety, increased health-related quality of life, and improvement in biomarkers (albumin, hemoglobin, potassium, and phosphate) [64].

Innovative ways for utilizing MI in clinical practice are also being trialed within CKD clinical settings. In a feasibility study conducted at a rural medical center, investigators working with patients who had stages 1–3a CKD paired dietary logging via smartphone with weekly telephone-based MI sessions delivered by registered dietitians over 8 weeks [65]. Results of this small study were promising, with 88% of the sample recording dietary data on at least 75% of the days. Patients also reported high levels of satisfaction with the intervention, and improvements were found in overall sodium intake, weight, and daytime systolic and diastolic blood pressure. This study, along with other published work on the use of MI in the context of healthcare, demonstrates the versatility of MI in that it can be employed by a variety of health-care professionals and in various formats (face-to-face, telephone).

### Future research directions in kidney disease management

Despite these applications of MI in kidney disease management, there are still additional areas to be explored. It is unclear if the beneficial impact of MI on CKD outcomes changes when morbidity with other chronic diseases (other than diabetes) is present. While it may be assumed that chronic disease profiles that have similarities in behavioral self-management (e.g., nutrition and physical activity requirement, medication adherence, and tracking) would also improve, the impact of MI on other co-occurring conditions like chronic pain, depression, anxiety, and cancer is less clear. It is possible that the mechanisms that significantly contribute to the effectiveness of MI (i.e., change talk) may not be the same mechanisms when working with patients with complex medical histories. Furthermore, given the higher incidence and prevalence rates of end-stage renal disease among non-Whites within the United States and the United Kingdom, further research to identify ways of utilizing MI to mitigate the progression of CKD among these populations is warranted.

Additionally, current literature focuses on MI-training at the nursing level likely due to the frequency of contact that nurses have with patients undergoing CKD treatments. Future work in kidney disease should focus on MI training at the physician, dietitian, pharmacist, and caregiver level. This expansion in training complements the increased focus on patient-centered

care that is embodied in the spirit of MI. Additionally, MI training can empower members on the treatment team by offering them tools to support patients in navigating the complexities in CKD management. It is possible that the positive impact of MI on disease outcomes can be further actualized by having a full clinical and family/caregiver team to affirm self-management skills and reinforce change talk.

Another area of potential research is the use of MI to delay CKD disease onset (e.g., patients at risk for CKD with comorbid diabetes mellitus type 2), or delay the progression of disease (e.g., predialysis or transplant). In doing so, longitudinal studies could examine how different elements of MI can serve as a preventative tool (vs an interventional tool) and whether behavior changes are sustained over time.

### Learning motivational interviewing

The complexity of treatment regimens has remained unchanged, and as such, the need for providers to be trained in effective strategies to engage patients in chronic disease management remains. Providers must be trained to understand how patients process all the information provided to them, and on what basis they make decisions about how to act in response to that information so that an effective collaboration is established. There has been increasingly more research examining the relative contribution of person-centered care to the effectiveness of MI [66], as well as other counseling modalities (including illness-integration, and guided self-determination) [67].

Literature on how to train providers in MI is well established. The most popular approach has been the use of several day workshops. Research on the effectiveness of MI workshops (expert-facilitated didactics and skill-building activities delivered in a group format) shows providers consistently improve their attitudes, knowledge, and confidence in MI, but immediate skill gains resulting from the training diminish within a few months [68–70].

A recent meta-analysis of MI training studies showed that the addition of approximately monthly post-workshop supervisory feedback and coaching sessions over a 6-month period was sufficient to sustain workshop training effects, with an overall MI skills training effect size of 75 [68]. Others have found that coaching MI-trained clinicians on their skills throughout the intervention results in greater beneficial effects, especially with medication adherence [71].

Several provider performance rating scales are now available that can be used to reliably supervise MI practice in this manner [72–75]. This approach to supervision is particularly important given that

providers typically evaluate their performance more positively than when the same sessions are reviewed by their supervisors or independent judges [76]. Moreover, in the absence of supervision in MI, providers may be more prone to initiate informal discussions (i.e., chat) about matters that are unrelated to their patients' treatment [76–78].

Even with supervision, providers will vary in their capacity to learn MI. For example, Miller has speculated that a minimum level of pre-training empathic abilities might be necessary for providers to learn MI [79]. In addition, learning MI may require that providers sequentially build their skills in different stages. Miller and Moyers proposed eight stages (see Table 47.2) for learning MI [80]. First, providers need to develop openness to the spirit of MI such that they grasp the overriding philosophy of the approach (stage 1). Next, they must master the patient-centered counseling skills embodied in the OARS (stage 2), the foundation from which they then learn how to recognize and reinforce change talk (stage 3). Providers then learn strategies for evoking change talk (stage 4), dancing with discord (stage 5), and developing a change plan (stage 6). Training in consolidating and strengthening commitment comes next (stage 7). If MI is to be used with other treatment approaches, learning how to switch between the methods or integrate MI into other practices is the last stage (stage 8). Providers may vary in the sequence and degree to which they learn the

skills embedded within each stage. Nonetheless, the stages of learning MI imply a training progression that might be used to organize the design of training programs. Moreover, they suggest that MI involves a complex set of skills that providers must use flexibly and adaptively in response to what patients say during their health-care appointments.

A variety of training resources exist to learn MI. These resources include textbooks, treatment manuals, training videotapes, a supervision toolkit, and an international training group called the MI Network of Trainers (MINT). Many of these resources are accessible at [www.motivationinterview.org](http://www.motivationinterview.org).

Dissemination of motivational interviewing

MI has become very popular in the United States and internationally. Single State Authorities throughout the United States and their equivalent bodies in other countries frequently recommend MI as an empirically supported clinical approach they want providers to learn [58–61]. The MINT has garnered international appeal, with the training of new trainers occurring internationally each year. It may be that the person-centeredness of the approach and, hence, sensitivity to diverse cultural perspectives make MI broadly attractive among various cultural backgrounds [81]. Moreover, the number of publications about MI has increased exponentially in the past three decades as well as funded research grants examining applications of MI to a variety of clinical problems and populations.

TABLE 47.2 Eight stages of learning motivational interviewing (MI) [80].

Stage	Definition
1	Developing an openness to interacting with patients with a spirit of collaboration, respect for autonomy, assumption of motives for change, and compassion
2	Developing proficiency in the use of patient-centered counseling skills such as open questions, affirmations, reflections, and summary statements
3	Recognizing and differentially reinforcing change talk as it naturally occurs in conversation and in the context of a patient's ambivalence
4	Eliciting and strengthening change talk in a goal-oriented fashion using a variety of techniques
5	Rolling with resistance using various strategies to avoid provoking arguments
6	Developing a change plan once a patient has made a clear commitment to change
7	Consolidating commitment to the patient's specific change plan
8	Switching between MI and other counseling methods as one moves beyond MI or returns to it when motivation wanes

Conclusion

MI is a recognized evidence-based practice for addressing behavioral problems that holds great promise for motivating patients with kidney disease to adhere to various aspects of the complex treatment regimens and other healthy lifestyle activities that are important for these patients. MI has a clear set of principles and strategies that guide implementation and substantial training resources to prepare providers to conduct MI proficiently. The popularity of MI continues to grow and the health-care field remains challenged to study if and how it works within its new applications, such as for the management of kidney disease, and to ensure that providers implement it with integrity to improve treatment outcomes. The nephrology community should learn how to apply MI techniques in CKD clinics and dialysis facilities. Carefully done studies will then need to be done to document the impact of MI on a variety of patient outcomes.

# Anorexia and appetite stimulants in chronic kidney disease

Juan Jesús Carrero<sup>1</sup> and Ailema González-Ortiz<sup>2</sup>

<sup>1</sup>Division of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden <sup>2</sup>Nephrology and Mineral Metabolism Department, Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, Mexico City, Mexico

## General considerations

Diminished appetite in patients with chronic kidney disease (CKD) is an important contributor to inadequate nutrient intake that leads, together with other concurrent risk factors, to the uremic protein-energy wasting (PEW) syndrome. Anorexia, nevertheless, is a complex term that involves not only metabolic signals but also anomalies in the system organs involved in nutrient intake as well as psychological and acquired aspects. Before discussing the intricacies of anorexia in CKD, we will briefly review the normal regulation of the feeding–hunger cycle.

## Normal regulation of the feeding–hunger cycle

The regulation of appetite involves a heterogeneous feedback system that requires the participation of signals from the gastrointestinal tract, liver, circulating nutrients, fat stores, interleukins (ILs), and metabolizing cell products, all of which are integrated in the hypothalamus, inducing hunger or satiety [1–4] (Fig. 48.1). In a simplified way the hunger–satiety cycle starts in with the desire to eat, induced among others by ghrelin secretion. When the meal reaches the stomach, stimulates satiety signals: meal volume and composition induce distention and stimulate baroreceptors, cholecystikinin (CCK) release by duodenal cells, and peptide YY (PYY) release by ileum/colon cells, all of which inhibit gastric motility. These signals induce in addition central satiety via the vagus nerve. At a next step, satiety is further induced by circulating

nutrients and metabolic end products, which regulate appetite by inducing gastrointestinal and liver peptide release (CCK, glucagon, and insulin). The gut-secreted incretins glucagon-like peptide-1 (GLP-1) and glucose-dependent insulintropic polypeptide, which activate glucose and insulin, release and increase intracellular ATP concentration, which again stimulates the vagus nerve and inhibits appetite.

Within the central nervous system (CNS), the melanocortin pathway located in the arcuate nucleus of the hypothalamus is a principal nexus through which nutritional cues converge and signal to influence food intake and energy balance. Two important pathways are induced at this level, the melanocortin receptor-4 (MCR-4) and proopiomelanocortin (POMC) pathways. Under normal conditions the activity of MCR-4 is increased by the suppression of orexigen hormones such as neuropeptide Y (NPY) and agouti-related protein (AGRP)-like activation of POMC-expressing neurons to produce  $\alpha$ -melanocyte-stimulating hormone. This directly stimulates melanocortin-4 receptor (MC4-R), causing increased energy expenditure and reduced food intake.

POMC and AGRP neurons, and the induction of the MC4-R pathway represent the essence of the hunger–satiety cycle. They are responsive to nutritional signals, including adipose (such as adipokines and cytokines), stomach, gut (such as ghrelin, PYY<sub>3–36</sub>, CCK, GLP-1) and pancreatic hormones (insulin, amylin), brain-derived energy balance–associated neurotransmitters and neuropeptides (such as catecholamines, GABA, serotonin, and NPY), dietary nutrients, and probably yet uncharacterized molecules [5,6].

**FIGURE 48.1** Gut-, liver-, and adipocyte-derived hormones, reflecting short- and long-term nutritional status, respectively, circulate in the periphery and signal to specific receptors in the brain. In the context of end-stage renal disease, there is evidence suggesting that the majority of these mediators are increased in circulation, either by simple retention or hyperproduction. CCK, cholecystokinin; GLP-1, glucagon-like peptide-1; PYY<sub>3-36</sub>, peptide YY residues 3–36. Source: Modified from Yeo GS, Heisler LK. Unraveling the brain regulation of appetite: lessons from genetics. *Nat Neurosci* 2012;15(10):1343–9.

To complete these biochemical pathways and illustrate the complexity of appetite regulation, the timing and amount of the next eating episode is not only dependent on internal factors, but to a large extent is also determined by external (conditioned) environmental and cultural (i.e., habits and traditions) cues. Humans eat not only to satisfy their appetite but also for many other reasons, for example, sensory hedonics, sensory stimulation, social pressure, mood, and boredom [1–3]. Last, but not least, problems in dentition, palatability, olfactory function, gastrointestinal tract, etc. are likely to influence both the willingness and choice of food as well. Thus anorexia is hard to quantify and also treatment of anorexia is complex and must involve a global multifaceted approach.

### Methods of appetite assessment in studies involving patients with chronic kidney disease

Appetite can be measured in two ways. First, it can be measured with the help of subjective ratings. When used appropriately, subjective ratings have been shown to be reproducible, sensitive to exposures of food components, and predictive of food intake. However, it should be noted that appetite may not always be accessible to patient introspection and that people do not always eat when they are hungry and do not always refrain when satiated. Second, appetite can be measured by actual food intake. The degree to which food intake reflects appetite is nevertheless debatable, as there are many factors that may intervene: cognitive factors such as dietary restraint and external factors such as availability, hedonic properties of food, and social circumstances.

Research methodology on anorexia usually includes rating scales to assess appetite, such as the visual analog scale (VAS) [7,8]. More inaccurate, but perhaps easily implementable in the clinical setting, is the use of self-reports of the patient's appetite [9–12], which have shown to validly correlate with both dietary energy and protein intake [10]. The simplicity of this question is as follows: “How would you grade your appetite in the last week?” adhered to a 4-point scale: (1) good, (2) sometimes bad, (3) often bad, and (4) always bad [9].

### Prevalence of anorexia and clinical implications in patients with chronic kidney disease

Anorexia is a common finding in CKD patients which typically develops when glomerular filtration rate is less than 10%–25% of normal and increases in severity with the progression toward end-stage renal disease (ESRD) [13]. While the prevalence of this condition in early CKD stages is, to our knowledge, unknown, it is reported in generally 35%–50% of the patients on dialysis [14] as shown in contemporary studies (Fig. 48.2), with a higher proportion of self-reported poor appetite on dialysis-treatment days [15]. The consequences of anorexia in this setting are important and should not be underestimated. Four medium–large sample size studies consistently show that a worsening in appetite progressively associates with increased mortality risk [8–10,12] (Fig. 48.3). Opposing to this, a subsequent recent study did not observe this mortality association in incident dialysis patients [16], but self-reports of appetite during the first days of dialysis initiation may be influenced by the

FIGURE 48.2 Reported prevalence of diminished appetite in ESRD, PD, and HD patients from various cohort studies. ESRD, End-stage renal disease; HD, hemodialysis; PD, peritoneal dialysis.

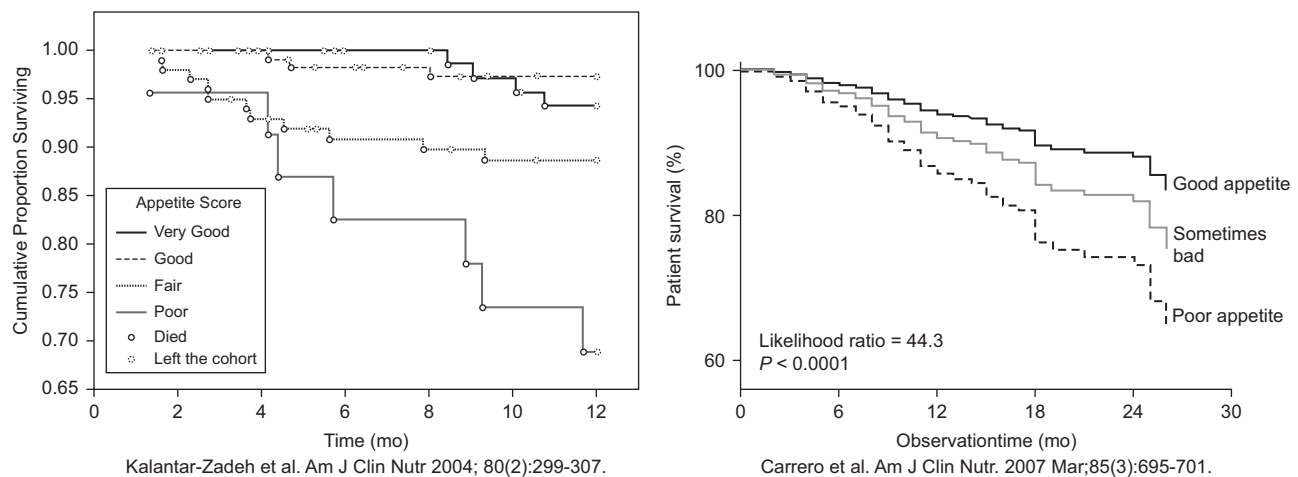

FIGURE 48.3 Kaplan–Meier survival curves from two studies showing the impact that a single self-report on patient’s appetite has on the prediction of 1-year and 2-year mortality. Both studies included prevalent patients undergoing hemodialysis. Source: Reproduced with permission from Carrero JJ, et al. Comparison of nutritional and inflammatory markers in dialysis patients with reduced appetite. Am J Clin Nutr 2007; 85(3):695–701; Kalantar-Zadeh K, et al. Appetite and inflammation, nutrition, anemia, and clinical outcome in hemodialysis patients. Am J Clin Nutr 2004;80(2):299–307.

overwhelming experience that the patients are being exposed to. In addition, anorexia increases hospitalization rates by up to 22%, with the costs that this implies for healthcare [10,12,17]. Finally, anorexia is perceived by dialysis patients as a significant worsening in their quality of life [8,11]. Ultimately, anorexia results in diminished and inadequate nutrient intake, resulting in important macro- and micronutrient deficiencies that contribute to the PEW syndrome [18].

### Pathogenesis of anorexia in chronic kidney disease

A spontaneous decrease in dietary protein intake and appetite occurs with progressive reduction in renal function [19,20]. Traditionally, diminished appetite has been considered a sign of uremic intoxication [21]. However, anorexia cannot be confined only to appetite regulators, as it links to several other important complications of CKD that need to be put in

**TABLE 48.1** Summary of potential mechanisms contributing to diminished appetite and undernutrition in chronic kidney disease (CKD) patients.

Causes of anorexia in CKD	Comment
<b>Disrupted molecular signaling</b>	
Altered CCK, PYY, ghrelin	Satiety arises earlier in dialysis patients during meal consumption. Ghrelin administration may have potential as therapy
Cytokine and adipokine retention	By both central and peripheral mechanisms. Potential as therapy through antagonism of the melanocortin-4 receptor
Low branched-chain amino acids	Leading to increased serotonin (appetite suppressant) production. Potential as therapy by oral supplementation
<b>Factors inherent to the dialysis procedure</b>	
Glucose absorption in dialysate	Feeling of fullness, inhibition of appetite by glucose degradation products, delayed gastric emptying by dialysate exchange
Retention of uremic suppressants/toxins	Unknown molecules of middle size
<b>Alterations in the organs involved in nutrient intake</b>	
Oral manifestations: taste abnormalities, dry mouth, tongue coating, mucosal inflammation, or oral ulceration	Problems with swallowing and food perception. Possibilities for treatment
Tooth problems: missing/decayed teeth, periodontitis	Problems with chewing, patient may avoid high-fiber foods. Possibilities for treatment
Impaired olfactory function	Affects taste and food perception. Related to systemic inflammation and malnutrition in CKD
Functional gastrointestinal disturbances: gastric distension, constipation, motility disorders, and impaired gastric emptying, diabetic gastroparesis	Will influence patients in their choice of food items that may associate with painful digestion/evacuation. Possibilities for treatment
Infections in the gastrointestinal tract	Possibly contributing also to systemic inflammation. Possibilities for treatment
<b>Social, psychosocial causes</b>	
Depression and anxiety, attitude toward disease	
Poor physical activity	
Loneliness and limited ability to do daily living (cooking, buying groceries, etc.)	
Economical limitations	
Poor nutritional knowledge on available food choices	

CCK, Cholecystokinin; PYY, peptide YY.

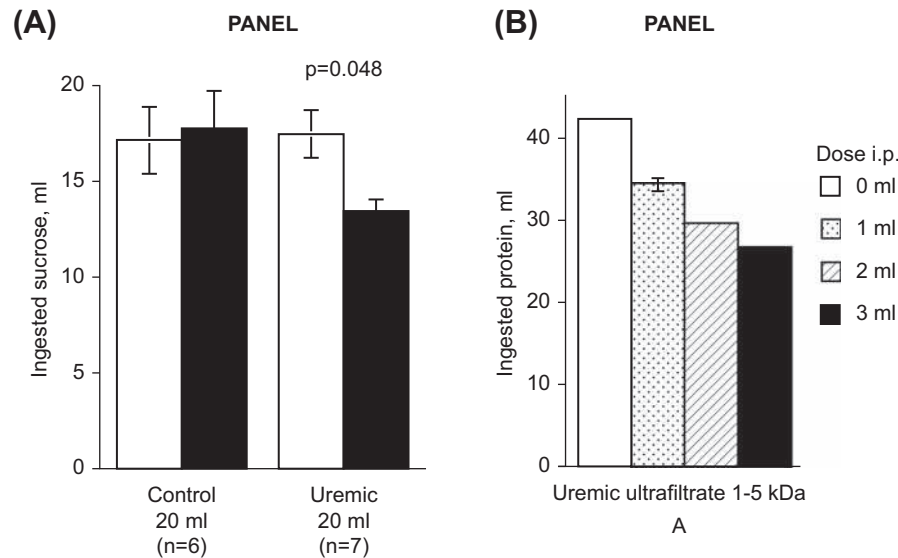

context. A correct understanding of the multifactorial causes of uremic anorexia is necessary to appropriately tackle this problem. Multiple causes of diminished appetite in the uremic population are discussed later and summarized in [Table 48.1](#).

## Retention of uremic toxins

Earlier animal and human studies identified retention of uremic toxins as a determinant of anorexia in ESRD [19,20]. Anderstam et al. [22] showed that rats given an intraperitoneal injection of plasma ultrafiltrate from uremic patients decreased food intake, as opposed to rats injected with plasma ultrafiltrate from healthy volunteers ([Fig. 48.4](#)). After the initiation of maintenance dialysis, food intake and nutritional markers usually improve, although not fully, indicating that dialysis removes certain anorectic toxins, but not all. Similarly, it can be hypothesized that the accumulation of these appetite suppressors may reach its maximum peak before each hemodialysis (HD) treatment, and indeed food intake is lower during HD days [15].

Dialysis patients show *slower eating* and *increased feeling of fullness* before the meals as compared to non-CKD patients [23] ([Fig. 48.5](#)). Early satiety and slow gastric emptying in dialysis patients have been linked to the dysregulation of short-term appetite modulators from the *gastrointestinal* tract, all of which seem elevated in ESRD patients likely because of uremic toxin retention. CCK levels were increased as compared to control individuals and associated with fullness and hunger perception in peritoneal dialysis (PD) patients [24]. PYY levels were also significantly elevated versus control individuals in HD patients [25], and meal provocation studies disclosed a marked dysregulation of PYY during the postprandial secretion in these patients [26], leading to earlier satiety and lower food intake than their age- and sex-matched controls.

*Ghrelin* is a gut orexigenic peptide that increases appetite and adjusts both short- and long-term energy balance through the expression of orexigenic neuropeptides and increased growth hormone release. A more in-depth review on the biology of ghrelin and its complex associations with various pathophysiological pathways of uremia is suggested here [27]. Ghrelin levels are elevated in dialysis patients presumably due to retention [28]. However, postprandial ghrelin regulation in dialysis patients does not differ from that of controls [29]. Given that ghrelin increases appetite, the elevated levels found in ESRD patients have been interpreted as a sign of resistance to the action of ghrelin. However, it is likely that other concurrent conditions, such as preexisting PEW, may have masked and confounded these observations in cross-sectional

**FIGURE 48.4** Anorexia as a sign of uremic intoxication. Rats given an i.p. injection of plasma ultrafiltrate from uremic patients with decreased food intake, as opposed to rats injected with plasma ultrafiltrate from healthy volunteers (A). This inhibition of food intake seemed to be dose-dependent (B). i.p., Intraperitoneal. Source: Reproduced with permission from Anderstam B, et al. Middle-sized molecule fractions isolated from uremic ultrafiltrate and normal urine inhibit ingestive behavior in the rat. *J Am Soc Nephrol* 1996;7(11):2453–60.

**FIGURE 48.5** Mean fullness scores at hourly time points for healthy controls (closed diamonds) and patients undergoing peritoneal dialysis (open circles) during a full day. While fullness and satiety peaks in healthy controls are marked by each episode meal (i.e., breakfast, lunch, and dinner), such peaks are much flattened in peritoneal dialysis patients, meaning that they have a general feeling of fullness along the day and a weaker eating drive. Statistically significant differences ( $P < .05$ ) by means of *t*-tests were observed in the change in fullness rating at lunchtime. Source: Reproduced with permission from Wright M, et al. Disturbed appetite patterns and nutrient intake in peritoneal dialysis patients. *Perit Dial Int* 2003;23(6):550–6.

analyses [30]. Ghrelin circulates in plasma in two major forms: acyl ghrelin, which promotes food intake, and the abundant desacyl ghrelin (>90%), which on the contrary may induce a negative energy balance by decreasing appetite and delay gastric emptying [31]. Consequently, desacyl ghrelin levels have been found elevated in anorectic HD patients as compared to

nonanorectic ones [32]. Interestingly, the acyl-ghrelin form was reported lower in HD patients and did not exhibit the premeal spike as observed in healthy controls [25].

Of the long-term regulators of appetite, hyperleptinemia ensues in advanced CKD due to decreased renal clearance [33]. *Leptin* is produced by adipocytes and provides information on the availability of body fat stores to the hypothalamus. A detailed discussion of leptin's biology and implication in CKD is given elsewhere [34,35]. Although *leptin* appears as an important central mediator of anorexia in animal models [36], human data on leptin in relation to uremic anorexia and PEW are so far inconclusive. Hyperleptinemia does not seem to be associated with worse appetite or worse nutritional status in dialysis patients [37–39]. It has been proposed that because anorectic patients are subjected to increased loss of body fat, leptin will primarily reflect fat stores in the catabolic uremic milieu and obscure any real link to eating behavior [40,41]. Although elevated leptin levels may be a consequence of other concurrent risk factors and share links with systemic inflammation [33], antagonizing leptin receptors at the hypothalamus may represent a future therapeutic target as discussed later. *Visfatin* is not only an adipokine but also an intracellular protein upregulated in times of low-nutrient availability, which gets activated to promote cell survival during starvation [42]. *Visfatin* concentrations have been found in human cerebrospinal fluid (CSF) and are linked to both appetite and body weight regulation [43]. In ESRD patients the reported hypervisfatinemia [44] may be a counter-

regulatory response to central visfatin resistance, because elevated (instead of reduced) visfatin levels were associated with anorexia and low fasting serum amino acids (AAs), glucose, and blood lipids, altogether indicating reduced plasma nutrient availability [45]. For both the cases of visfatin and leptin, conditions typical of advanced CKD can cause the inhibition of brain-to-blood transport, leading to the accumulation of endogenous metabolites and drugs in the brain [46]. It is possible that central action of these and other orexigens may be hampered by uremic toxicity.

Imbalances in serum AA profile may contribute to a “brain hyperserotonergic-like syndrome” that favors anorexia in ESRD. The altered AA pattern in CKD includes reduced essential/nonessential AAs ratio and lower branched-chain AAs [47], which would theoretically favor high levels of free tryptophan in the CSF. Tryptophan is the precursor of serotonin, a mediator of appetite suppression. In addition, the nitric oxide (NO) system is altered in CKD, with the accumulation of NO synthase inhibitors that interfere with tryptophan metabolism and enhance serotonin production [21]. While this hypothesis has not been confirmed in CKD [47], the fact that oral branched-chain AA supplementation improved energy intake and nutritional status in a small placebo-controlled double-blind study of malnourished dialysis patients [48] may indicate its potential beneficial role.

Some appetite-related nervous system–derived hormones also seem to be altered in advanced CKD. Increased NPY levels along with a lack of circadian variation [25] have been reported in HD patients [25,49]. Norepinephrine levels have been reported elevated in HD patients but did not exhibit the normal nocturnal dip either [25]. Finally, it has been proposed that the commonly observed suppressed parasympathetic activity in CKD patients may contribute to anorexia [25]. Interestingly, a recent animal study observed marked neurodegeneration in the anorectic *anx/anx* mouse accompanied by the generation of reactive oxygen species (ROS) and subsequent dysfunction in the mitochondrial oxidative phosphorylation system [50]. It is interesting to speculate that ROS in advanced CKD may parallel some of these observations as also encountered in human anorexia nervosa.

### Alteration in the organs involved in nutrient intake

A number of abnormalities commonly present in CKD may indirectly affect and/or mask the feeling of hunger in ESRD patients, likely influencing and limiting dietary intake. The enjoyment of food depends not only on its taste but also on its odor as it approaches

the mouth and the release of volatile organic substances within the mouth. In addition, the temperature and texture of the food, as well as the masticatory sounds, all produce the ultimate sensory experience. All of these factors seem altered in ESRD such as taste abnormalities (palatability, acuity, and metal flavor), dry mouth, tongue coating, mucosal inflammation, or oral ulceration (that will altogether ultimately lead to swallowing problems), which can all contribute to inappetence. Taste loss is common in ESRD [51,52], and its strong association with kidney function suggests that the retention of uremic toxins may be responsible [51].

Typical *dental problems* such as decayed, missing, or filled teeth and the increased prevalence of periodontitis in the CKD population likewise create chewing and/or biting problems, making patients less likely to consume high-fiber foods such as bread, fruits, or vegetables and, therefore, risking their essential nutrient intake [14]. *Olfactory function* is also impaired in HD patients and related with the severity of PEW [53]. The recent observation that olfactory dysfunction in ESRD is readily reversible by the HD session [54] challenges, however, this hypothesis.

Loss of appetite in uremia is related to a number of common *gastrointestinal disturbances*, including gastroesophageal reflux, gastric distension, constipation, motility disorders, and impaired gastric emptying [55–57], all of which will create discomfort associated to nutrient digestion and subsequent food aversion. *Chronic diabetic gastroparesis* may be an important problem resulting in reduced nutrient intake. With prolonged diabetes the vagus nerve becomes damaged and develops autonomic neuropathy. This disturbance results in prolonged abdominal distension and exacerbated feeling of satiety. Other indirect causes of anorexia may relate to stomach irritation caused by medications, such as iron compounds or phosphate binders. Gastrointestinal infections are important and underappreciated contributors to anorexia in CKD. In the study by Aguilera et al. [58], *helicobacter pylori* infection in PD patients was associated with a poor nutritional status, increased systemic inflammation, and worse appetite scales. *Bowel bacterial overgrowth syndrome* was also associated with anorexia and inflammation in PD patients [59]. CKD in itself profoundly alters the intestinal barrier structure and the microbial flora [60,61]. The biological impact of these phenomena is largely unknown but it is possible that they may play a major role in the pathogenesis of inflammation and uremic toxicity [60], which may per se induce appetite loss. Recent studies also indicate that short-chained fatty acids produced by the microbiome can induce the release of GLP-1 from

cells in the colon, which raises the possibility of an even greater influence of our microbiome with the body's energy metabolism and immune system [62].

### Medications and dialysis

Drugs can affect food intake, and food intake can also affect the efficacy of some drugs. Most CNS stimulants lead to appetite loss, and certain antihypertensive drugs (captopril) may result in abnormalities in taste/smell of food. Drugs such as codeine and morphine can decrease peristalsis causing constipation. Drugs can also affect absorption, metabolism, and excretion of nutrients: NSAIDs can alter gastric acidity impacting on intestinal mucosa, and antibiotics can bind to some nutrients such as Fe, Mg, and Zn with ensuing difficulty in their absorption. Others, like corticosteroids, may actually increase appetite.

The dialysis procedure may further aggravate anorexia. Animal studies demonstrated that PD solutions with increasing glucose concentration gradually inhibit ingestive behavior [63] (Fig. 48.6). Generation of glucose degradation products (GDP) has been suggested as mediators of uremic anorexia, as heat sterilization of glucose PD solutions (thus increasing GDP production) inhibited intraoral intake in mice in a dose-dependent manner as compared to filter sterilization [64]. Although there is no strong evidence suggesting that PD patients have worse PEW compared to HD patients, it seems that PD patients are more often bothered by diminished appetite and gastric discomfort [21,65–67]. PD fluid exchange has been shown to delay gastric emptying and, thus, leads to fullness interfering [29,68]. Practically no studies have been performed investigating whether HD induces appetite loss, but the absence of evidence does not mean evidence of

absence. HD patients often skip one meal in connection with their dialysis session [69].

### Psychosocial factors and comorbidities

ESRD patients are a heterogeneous population where concomitant illness such as cancer, heart/vascular disease, or diabetes may contribute to the onset of anorexia. While some studies do not associate anorexia in uremia with comorbidities [9,11,16], an increased prevalence of diabetics across worsening appetite scores was reported in the Dialysis Outcomes and Practice Patterns Study [10]. Also, age and comorbidities were higher among anorectic HD patients from Italy [17]. Thus a last consideration is that CKD is eminently a disease of the elderly [63,64], and altogether it may be difficult to separate CKD-induced appetite loss from the diminished appetite and nutritional derangements that naturally develops with aging and disease.

*Depression* (Fig. 48.7) and *anxiety* will obviously influence the willingness to eat, and observational reports show that appetite is, in fact, poorer when patients score worse on their depression tests [12,70]. Common alterations in ESRD such as low thyroid hormone levels [71] may also influence food intake. Additional factors, more difficult to evaluate and to treat, that may promote low-nutrient intake are loneliness (living alone, widow or divorcee, and social isolation), limited ability to do activities of daily living (manage themselves, cook or buy groceries), or economic restraints. Lack of education on adequate dietary needs and CKD-specific dietary restrictions can result in poor dietary intake with an inadequate selection of food choices. Diseases that interfere with the ability of the person to eat or prepare food, for example, stroke, tremors, or arthritis, can also lead to decreased food intake.

Source: Reproduced with permission from Zheng ZH, et al. Acute effects of peritoneal dialysis solutions on appetite in non-uremic rats. *Kidney Int* 2001;60(6):2392–8.

### Systemic inflammation

An increased loss of appetite is associated with elevations in biomarkers of systemic inflammation [9,11,72,73] (Fig. 48.8). Besides many other implications in the organism [74,75], proinflammatory cytokines are capable of inducing anorexia by both central and peripheral mechanisms. Central mechanisms are mediated by the direct effect of cytokines on hypothalamic neurons and/or the generation of mediators targeting brain target sites [21,76]. At a nuclear level, nuclear factor kappa B activation also suppresses food intake, at least in mice, by direct activation of the POMC promoter at the hypothalamus [77]. In addition, peripheral mechanisms have to do with the effect of inflammation on the ESRD-related complications that contribute to

**FIGURE 48.7** Lack of appetite is associated with signs of depression. **FIGURE 48.8** Markers of systemic inflammation increase across worsening appetite categories in a cohort of patients undergoing maintenance hemodialysis. Source: Adapted from Carrero JJ, et al. Comparison of nutritional and inflammatory markers in dialysis patients with reduced appetite. *Am J Clin Nutr* 2007;85(3):695–701.

anorexia [78]. For instance, in dialysis patients, depressive symptoms correlate to increased IL-6 levels [79]. Chronic inflammatory processes in the periodontium are associated with an elevation of inflammatory biomarkers in HD patients [80]. Impaired olfactory function associates with inflammation [53], and CRP directly blocks the effects of leptin upon satiety and weight reduction [81], suggesting a link between

systemic inflammation, leptin resistance, and CKD. Alterations in the gastrointestinal tract, such as dyspepsia and nausea, were associated with increased inflammatory response biomarkers in dialysis patients [82]. IL-1 and TNF interfere with tryptophan and serotonin turnover [83]. TNF decreases NO levels and increases sympathetic activity [84], and low serum AAs are, in part, consequence of systemic

inflammation [85]. Altogether, these interactions emphasize the importance of the interplay between inflammation and PEW and its role in exacerbating poor outcomes [86]. Accordingly, it can be speculated that systemic inflammation may constitute an integrative factor in the development and worsening of poor appetite in ESRD patients.

### **Treatment of anorexia in chronic kidney disease**

The prodromal step for anorexia management is early identification. A simple inquire to the patient about his/her appetite in the last weeks may represent an alarm signal for further follow-up and assessment [9–12]. Such information is costless and can be done on a routine basis. Treatment of anorexia in ESRD is complex, and there are limited data for evidence-based approaches [87]. In Fig. 48.9, we propose several action points when treating anorexia in ESRD.

#### **Identify and treat underlying causes**

As a first step one should screen, identify, and if possible treat underlying causes of anorexia, including gastrointestinal infections and disorders, depression, poor oral and dental health, and the presence of periodontitis or diabetic gastroparesis. In the case of alterations in the GI tract, gastric motility agents, such as domperidone, metoclopramide or cisapride, and proton-pump inhibitors, may be used with caution and close monitoring. Two studies show the need for a more stringent screening and management of bacterial infections: general antibiotic treatment of *helicobacter pylori* infection and *bowel bacterial overgrowth syndrome* in PD patients

yielded important improvements in appetite scores and resulted in reduced systemic inflammation [58,59].

A comprehensive nutritional, dietary, and appetite assessment to determine the presence or absence of PEW is recommended. A detailed personal interview with the patients may help us to detect other psychological or social situations that further enhance low food intake, such as problems related to self-feeding, access to food, and eventually, identification of active psychic, social, medical, dialytic, or medicine-related issues that could affect food intake. Of note, the treatment of depressed HD patients with fluoxetine resulted in improved systemic inflammation and increased food intake [88,89].

In the case of diabetic gastroparesis, several recommendations can be given, including (1) to eat small frequent meals, since high volumes can slow gastric emptying; (2) to consider mechanically altered foods (pureed, ground); (3) not to limit fat, which can provide additional calories; and (4) to stand up for at least 1–2 hours after eating. If oral dietary modifications are not effective, current approved treatment options include metoclopramide and gastric electrical stimulation. Antiemetics, domperidone, or erythromycin may also produce symptom relief [90].

#### **Support and promote food intake and physical activity**

Nutritional counseling to correct reduced or unhealthy nutrient intake should be given to all patients on a regular basis as a mean to promote food intake and improve the patient's knowledge on food options with respect to their disease. Promotion of physical exercise and salutary

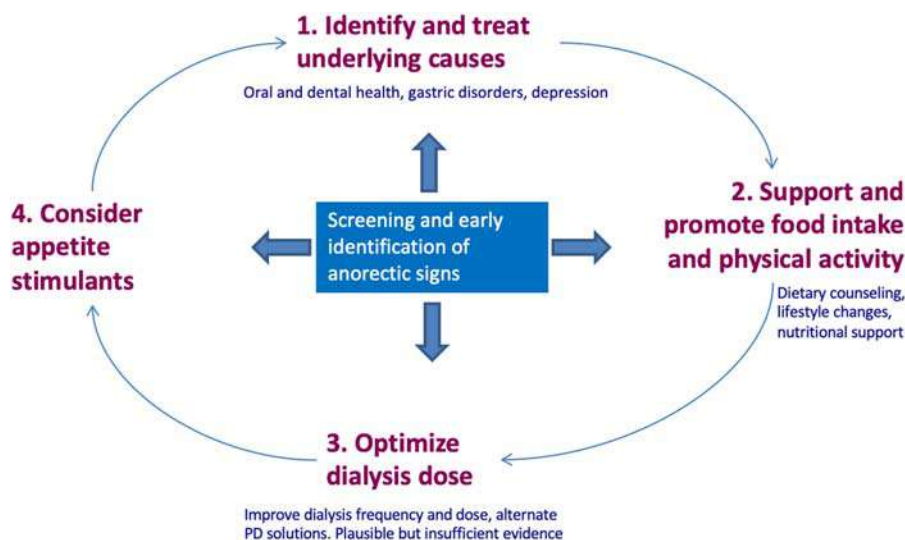

FIGURE 48.9 Proposed action points to treat anorexia in patients with CKD. At all phases, ongoing and frequent monitoring is a requirement to sustain optimal outcomes and adapt course of action. CKD, Chronic kidney disease.

lifestyle modifications may indirectly impact on the patients' energy and calorie intake through both improved general well-being [91].

Nutritional support in the form of oral supplements, parenteral nutrition, or intradialytic parenteral nutrition is a valid alternative to ensure adequate nutrition, and perhaps also to improve appetite. Alluding to the "brain hyperserotonergic-like syndrome" hypothesis earlier discussed, a randomized controlled crossover trial with 28 malnourished PD patients provided daily branched-chain AAs supplementation (12 g/d) for 6 months and resulted in improved nutritional status and increased spontaneous oral food intake versus placebo [48]. A more recent study also observed improvements in serum albumin and protein catabolic rate together with a decrease in CRP after the supplementation of oral AAs versus placebo [92]. Fish oil supplementation elicited meaningful trends toward improvements in subjective appetite in a noncontrolled study, including 28 HD patients from Australia [93], presumably via the antiinflammatory effects of  $n-3$  fatty acids.

Providing supplements to anorectic patients may be a way to initiate the wheel of food intake. It has been argued, however, that intake of oral nutritional supplements (ONS) promotes fullness and the patient would, in turn, skip a meal. Boudville et al. [94] addressed this issue in a crossover trial of 13 PD patients. Patients were given a standard ONS or placebo 2 hours or 30 minutes before lunch. Lunch was provided as a self-select buffet-style meal, and food intake was recorded and measured. Results showed that patients felt hungrier after the placebo drink than after ONS. Patients reported feeling fuller and less able to eat than before, especially when consuming ONS 30 minutes before the lunch. However, this did not significantly nor clinically influence the amount of subsequent food calorie or protein intake [94]. Nevertheless, alternatives to prevent a possible impact on appetite feeling may be to advice consuming ONS after the meals or during the dialysis session, and/or advice using ONS throughout the day instead of water to ingest medication.

## Optimize dialysis regimes

Optimizing dialysis regimes could potentially improve appetite in ESRD patients. Theoretically, increased dialysis adequacy may render not only an enhanced elimination of certain toxins and appetite suppressants, but also a general feeling of well-being, increased physical activity, fewer dietetic restrictions, and decreased dose of medications. The Hemodialysis (HEMO) Study showed that appetite scores were not differentially affected by increased

dialysis dose or flux. Although the average decline in equilibrated protein catabolic rate during follow-up was significantly less in the high dose than the standard dose group, the differences were subtle and neither intervention prevented deterioration in nutritional status over time [95]. It has been, therefore, suggested that dialysis frequency rather than dialysis dose may be more important in the improvement of nutritional status [96]. In fact, a number of small uncontrolled studies suggest that the increase in dialysis frequency through short daily HD or nocturnal HD may improve nutritional status, appetite, and food intake [97–100]. Molina et al. [101] randomized 33 adults with CKD Stage 5 undergoing maintenance high-flux HD to either postdilution online hemodiafiltration or to remain on high-flux HD for 12 months. Results showed that hemodiafiltration, compared with high-flux HD, preserved muscle mass, increased appetite (VAS scale) and protein intake, and reduced the inflammatory state related to uremia and dialysis, supporting the hypothesis that high convection volume can benefit nutritional status and prevent PEW in HD patients.

In PD, one study reported an improvement in appetite scales through applying increased daily dialysate volume [102]. Davies et al. [103] performed an open, prospective, "intention to treat" study in which malnourished (according to subjective global assessment) long-term anuric PD patients received an intended dialysis dose increase of 25% and were reassessed after 6 months. Dialysis dose was not increased in the remaining nonmalnourished patients, unless dictated by uremic symptoms. In this setting, increased dialysis dose increased dialysis-derived calories, stabilized body weight, and improved creatinine appearance. Oral calorie intake improved, as did plasma albumin after an initial decline. There was, however, no increase in protein intake, as judged by either dietetic interviews or protein nitrogen appearance. These modest effects on nutritional status were not supported by the results from the Adequacy of PD in Mexico study, in which albumin levels or nitrogen protein appearance did not improve after increased peritoneal clearance [104]. Alternation with nonglucose-based solutions has also been associated with increased nutrient intake and more anorexic profile in both animal studies and a recent randomized trial [64,105,106].

## Use of appetite stimulants

The use of appetite stimulants should be considered in anorectic ESRD patients where previous suggested steps have failed. Various pharmacologic agents are

available in the market, but megestrol acetate is the only one for which there are clinical studies in ESRD patients. Megestrol acetate is a synthetic hormone (progestogen) effects of which on appetite stimulation have mainly been studied on cancer cachexia. Table 48.2 summarizes available studies and main results with megestrol acetate in ESRD. All studies, including two randomized controlled trials, report improvements in appetite and dietary intake, weight gain, and serum albumin [107–114]. A limitation of these studies is their relatively small sample size. Although in principle megestrol acetate could be a valid option for treating anorexia in ESRD, caution is needed in the close monitoring and follow-up of patients for possible side effects. A few of these studies report cases of diarrhea, overhydration, hyperglycemia, ACTH secretion [113,114], and Cushingoid features in children [112].

Besides its orexigenic actions, ghrelin may favorably influence other pathways such as inflammation, vascular resistance, cardiac output, or growth hormone [115]. It is presently being considered a therapeutic agent in diseases such as cancer cachexia, chronic heart failure, or arthritis [115]. Available studies to date show beneficial effects but are limited in general by a reduced sample size and short duration. Initial evidence in dialysis patients suggests that

subcutaneous acyl-ghrelin administration improves short-term (single dose and 1-week treatment) energy intake and energy balance in patients with mild-to-moderate malnutrition [116,117]. These results, although promising, should be interpreted with caution until further research evaluates the safety and tolerance of long-term ghrelin administration in dialysis patients [118].

Central effects of both adipokines and cytokines on anorexia are mediated by the hypothalamic MC4-R system. Both the activated macrophage and the activated adipocyte secrete these molecules to plasma and, via the vagus afferent nerve, activate the melanocortin receptor system altering the balance food intake/energy expenditure. Pharmacologic manipulation has shown that agonizing the MC4-R causes weight loss and antagonizing the MC4-R produces weight gain. Interestingly, Cheung et al. [119] reported that intraperitoneal administration of MC4-R antagonists stimulated food intake and weight gain in uremic mice. Most interesting in this study is the secondary observation that neuropeptide signaling pathways also affected expression of key proteins involved in muscle mass maintenance [119], linking uremic anorexia, and muscle catabolism by common pathways. Multiple classes of MC4-R antagonists have been reported and

TABLE 48.2 Summary of reported studies using megestrol acetate as a mean to improve anorexia and nutritional status in patients with chronic kidney disease.

Reference	Number of patients (dialysis modality)	Dose	Study design	Outcomes
Boccanfuso et al. [107]	17 (HD)	400 mg/d for 6 months	Prospective observational	↑ Appetite and weight
Costero et al. [108]	32 (PD)	160 mg/d for 6 months	Uncontrolled	↑ Appetite and weight
Rammohan et al. [109]	10 (HD)	400 mg/d for 4 months	Uncontrolled	↑ Weight, albumin, energy intake, and quality of life
Monfared et al. [110]	22 (HD) hypoalbuminemic	80 mg/d for 2 months	Randomized controlled	↑ Albumin and protein catabolic rate
Yeh et al. [111]	9 (HD) wasted male patients	800/d for 5 months	Randomized controlled	↑ Weight (both fat and fat-free mass) and exercise capacity. ↑ Appetite and well-being (trends)
Hobbs et al. [112]	25 pediatric CKD patients	Tapered doses 14.4 mg/kg/d for 5.4 months	Retrospective observational	↑ Weight. <i>Side effects</i> : Cushingoid features ( $n = 1$ )
Golebiewska et al. [113]	12 (HD) hypoalbuminemic	160 mg/d for 6 months	Uncontrolled	↑ Weight, albumin, subjective global assessment. <i>Side effects</i> : overhydration, excessive weight gain, and hyperglycemia
Fernández Lucas et al. [114]	16 (HD)	160 mg/d for 3 months	Uncontrolled	↑ Weight, albumin, creatinine, and protein catabolic rate. <i>Side effects</i> : hyperglycemia and ACTH secretion

patented, but still it is too early to be able to apply these therapies in the clinical setting. In any case, hypertriglyceridemia- [120], inflammation- [81], and obesity- [121] associated hypothalamic leptin resistances need consideration and may explain the so far unsuccessful attempts with this hormone in human obesity. Given that some drugs such as cannabinoids, corticosteroids, or pentoxifylline exert both antiinflammatory and appetite stimulant effects, interventional studies are needed to assess its clinical application in the management of appetite and food intake in ESRD.

## Conclusion

Poor appetite is a common finding in ESRD patients. Anorexia leads to PEW and associates with worse clinical outcomes, including hospitalizations, quality of life, and death. Appetite regulation in ESRD is complex and multifactorial in origin. It is possibly initiated by the reduction in kidney function per se but later on evolves in a complex pathophysiology involving not only uremic toxin retention but also metabolic dysregulation alterations in the organs involved in nutrient intake and utilization as well as clinical depression. Regular enquires about patient's appetite by the nephrology team is warranted for early detection and appropriate management. At present, such management may require a thorough screening (and treatment) of underlying causes. Evidence on the use of appetite stimulants so far is scarce and limited to megestrol acetate.

# Herbal supplements in patients with kidney disease

Alison L. Steiber

Research, International and Scientific Advisory, Academy of Nutrition and Dietetics, Chicago, IL, United States

## Introduction

The impact of herbal supplements on kidney function as well as the interaction between herbal supplements and commonly used treatments for patients with kidney disease will be reviewed in this chapter. Herbal medicine, as defined by Jonas and Levin in the *Essentials of Complementary and Alternative Medicine*, is “a healing approach that uses medicinal plants singly or in combination to treat disease and as a preventive to promote health and well-being” [1]. Any form of the plant or plant product can be included in this definition; for example, the leaves, stem, flowers, roots, seeds, or even extract of the plant can be used to enhance health.

It is difficult to pinpoint the exact number of adults who use herbal medicines; part of the difficulty stems from a variety of terms used in research surveys. However, the use of herbal medicine in the general population, and specifically in those patients with chronic diseases, is thought to be very high. In a 2016 report from the Centers for Disease Control and Prevention, adults spent \$28.3 billion out-of-pocket on complementary health approaches; individuals with family incomes spent between \$50,000 and 9999 on such natural products (\$4.1 billion) as nonvitamin, nonmineral dietary supplements [2]. In both 2007 and 2012 the National Health Interview Survey reported that natural products were the most frequently used complementary health approach among adults and children; almost 18% of American adults and 5% of children used these products [3]. Of the adults using natural products, fish oil or omega-3 fatty acids were the most popular, at 7.8%.

Herbal medicine is often considered by the general public to be “more natural” and therefore “safe” when

compared to conventional medicine. Unfortunately, this way of thinking is flawed. Many of the herbal products on the market today have multiple ingredients, and these ingredients may or may not be present in sufficiently high concentrations to be pharmacologically active. An example of a herbal product having multiple chemicals was highlighted by Dr. Stephen Bent in a paper from the University of California, San Francisco Medical Center [4]. In this paper, Dr. Bent describes ginkgo biloba as containing at least 33 different chemicals.

In contrast to medications the Dietary Supplement Health and Education Act, passed in 1994, allows herbal medicines to be produced and sold without evidence of safety or efficacy. In fact, of the most commonly purchased herbal products sold in the United States, only 5 out of 10 products have evidence of efficacy (i.e., ginkgo biloba, garlic, St. John’s wort, soy, and kava kava) [4]. It should be noted that even the evidence for safety and effectiveness that does exist for individual herbal products has major limitations with regard to the information provided, concerning the methods for preparing the product, the methods for testing, and the primary outcomes from clinical studies on the product.

There are three basic ways in which herbal medicines may be unsafe: (1) due to the presence of contaminants [5]; (2) due to the presence of biologically active compounds; and (3) due to herbal-to-drug or herbal-to-herbal interactions. A recent example of the risk of contamination was outlined in a case study by Prakash et al. [5] where a patient presented with a significant decline in renal function and an abnormal presentation of symptoms. Upon investigation, it was discovered that the patient had been

consuming an Ayurvedic herbal product from India. Each tablet of this herbal product had 236.7  $\mu\text{mol}$  (49,000  $\mu\text{g}$ ) of lead, which had resulted in lead poisoning and subsequent rapid progression of kidney failure in the patient.

A well-documented negative effect of a biologically active compound, aristolochic acid, has been shown to cause Fanconi's syndrome nephropathy, characterized by proximal tubular toxicity, increased low molecular weight proteins in urine, and chronic renal interstitial fibrosis [6]. This compound was incorporated in Chinese herbals used for weight loss. In a case study describing 105 Belgium women taking the Chinese herbal, 43 developed end-stage renal disease and 39 underwent prophylactic nephrectomy [7].

Finally, with multiple chemical compounds in the herbal medicines, some of which are biologically active, it is not difficult to understand why there is a risk that these products may interact with drugs, foods, and other supplements. Herbals can interfere with absorption, metabolism, and potentially the excretion of other metabolites found in conventional medicines and in nutrients from food [1]. A classic example of a herbal product interacting with metabolism is St. John's wort that is degraded by the cytochrome P450 enzyme system in the liver and thus interferes with the metabolism of other drugs that are processed by the same system.

To more completely understand herbal metabolism, a brief discussion of the cytochrome P450 enzymatic system may be worthwhile, as both St. John's wort and aristolochic acid are nephrotoxic and are metabolized by this system. Cytochrome P450, a detoxifying system with subclasses that metabolize foreign toxins, is the most important xenobiotic-metabolizing enzyme system and is found primarily in the liver [8]. However, there are both cytochrome P450 systems and non-P450 enzymes in the kidney as well. This enzyme system is responsible for metabolizing many commonly used medications, such as morphine-derived pain-reducing agents, oral contraceptives, and chemotherapeutic agents [4].

The following is an overview of herbal supplements and how they relate to the kidney, with specific emphasis on acute kidney injury, chronic kidney disease (CKD), and kidney transplantation.

### **Acute kidney injury**

The acute effects on kidney function and injury of different herbal products, as described in various publications, are summarized in Table 49.1. This table illustrates the variety of reasons why people take these supplements, from weight loss to constipation to

diabetes, and the wide range of biological chemicals that have potentially negative side effects related to kidney health and function.

### **Aristolochic acid nephropathy**

Aristolochic acids are a family of structurally related compounds that are not uncommonly referred to as simply aristolochic acid. The adverse effects of aristolochic acids on the kidney are so characteristic and well documented that they have a proper name: aristolochic acid nephropathy (AAN). This type of nephropathy, previously called Chinese herbal nephropathy, usually presents with subacute renal failure with severe anemia or as Fanconi's syndrome and often results in rapid progression to end-stage renal disease [19,20]. Histological examination of the kidney with AAN indicates interstitial nephritis with severe fibrosis. The chronic kidney failure may be complicated by neoplastic transformation in the urothelium. Aristolochic acid is considered to be the cause of Balkan endemic nephropathy [8]. The products of aristolochic acid metabolism by cytochrome P450 are called aristolactams and are primarily found in urine and feces. It is unknown whether these metabolites are the cause of AAN or whether the aristolactams are further metabolized by the kidney, and the subsequent products of this metabolism cause the toxicity (see Fig. 49.1).

In 2001 the US Food and Drug Administration published a list of products containing aristolochic acid as a warning to consumers (see Table 49.2). On April 23, 2019 an alert was published by the Food and Drug Administration regarding aristolochic acid and its danger for kidney injury ([https://www.accessdata.fda.gov/cms\\_ia/importalert\\_141.html](https://www.accessdata.fda.gov/cms_ia/importalert_141.html)). This alert indicates that some manufacturers of food supplements still include aristolochic acids in their products, and that consumers and health-care providers need to be aware.

### **Herbal teas**

#### **Chronic kidney disease**

The use of herbs in the dialysis population is a particularly difficult challenge for both patients and health-care providers in terms of determining their safety and effectiveness. There is a paucity of data describing herbal excretion, dialytic clearance, and interaction with other drugs. In a 2007 study by Duncan et al. [21], dialysis patients were surveyed on complementary and alternative medicine (CAM) use. A total of 294 patients were given paper surveys, and 153 patients completed the survey (52%). Of the

TABLE 49.1 Herbal supplements and acute kidney injury.

Active compound	Herb/plant	References	Reason for use	Symptoms	Other
Aristolochic acid	<i>Akebia</i> species, Boui, Mokutsu, Mu-tong, <i>Aristolochia</i> species ( <i>Stephania</i> species)	Isnard Bagnis et al. [6]	Ingredient in herbal “slimming pills,” Chinese herbals for hepatitis B	Aristolochic acid-nephropathy: Fanconi’s syndrome, increased low-molecular weight proteins in urine, chronic interstitial renal fibrosis, proximal tubular toxicity	Also a risk factor for carcinomas of the urinary tract in animals and humans
Aloesin (aloeresin A/B)	<i>Cape aloes</i>	Luyckx et al. [6,9]	Laxative	Acute oliguric renal failure, interstitial nephritis (intravenous, IV administration)	
Sciadopitysin	<i>Taxus celebica</i>	Lin et al. [6,10]	Diabetes therapy	Acute tubular necrosis, fever, gastrointestinal (GI) upset, hemolysis	
Atractyloside	<i>Callilepis laureola</i>	Seedat and Hitchcock [6,11]	Vermifuge or purgative (Zulu)		
Glycyrrhizic acid/glycyrrhetic acid	<i>Glycyrrhiza glabra</i> , <i>Glycyrrhiza radix</i> (licorice), <i>Glycyrrhiza uralensis</i> (gancao)	Stewart et al. [6,12]	Cough mixtures, teas	Aldosterone-like effect, inhibition of renal steroid dehydrogenase enzyme, proximal tubulopathy	
Glycyrrhizic acid, aristolochic acid	Boui-ougi-tou (Chinese herbs/drugs mixture)	Stewart et al. [6,12,13]	Cure for obesity	Fanconi’s tubulopathy	
Ephedrine	Ma huang (usually as tea)	Powell et al. [14]	Asthma, cold/flu, fever/chills, aches, edema	Hypertension, kidney stones	
Anticholinergic substances (scopolamine, hyoscyamine, atropine)	<i>Datura metel</i> , <i>Rhododendron molle</i>	Chan et al. [15]		Acute urine retention	
	<i>Vaccinium macrocarpon</i> (cranberry)	Harkins et al. [16]		Oxalate stones in high-risk patients	
Paraphenylenediamine	Takaout roumia	Isnard Bagnis et al. and Sir Hashim [6,17]	Substitute for <i>Tamaris orientalis</i> in hair dye	Acute tubular necrosis, rhabdomyolysis	
Sodium or potassium dichromate	Substituted for herbal ingredients	Wood et al. [18]		Acute renal failure, albuminuria, pyuria, hematuria, interstitial nephritis	

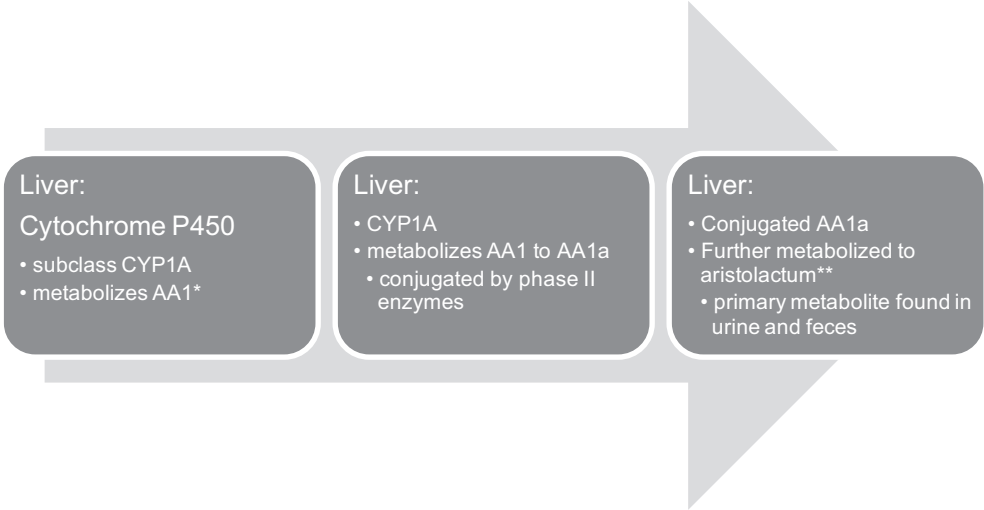

responders, 18% said they were currently using some form of CAM, 63% indicated they would be willing to try a type of CAM, and 19% said they would never use CAM. Of those who were currently using CAM, the most consumed herbals were St. John’s wort, ginkgo, vitamin B<sub>12</sub>, and melatonin. While these findings are interesting, the study sample was quite small with only 12 patients in the CAM user group. Thus the data cannot be generalized to the larger hemodialysis population. However, this study does highlight the importance of a thorough assessment of CKD and chronic dialysis patients to identify their use of herbal

supplements. Table 49.3 outlines herbs that may affect CKD patients who are receiving dialysis.

### Five herbals with some proven efficacy

#### St. John’s wort

St. John’s wort is primarily used as an antidepressant and multiple randomized clinical trials have shown it to be effective in relieving mild-to-moderate depression. A metaanalysis was conducted by Linde et al. [39], which reviewed the pertinent clinical trials to determine whether the active ingredient in St. John’s

**FIGURE 49.1** Metabolism of aristolochic acid. \*Aristolochic acid 1, the most toxic derivative of aristolochic acid. \*\*Exact location of this action is not known, possibly both the liver and kidney. Adapted from Xiao Y, Ge M, Xue X, Wang C, Wang H, Wu X, et al. Hepatic cytochrome P450s metabolize aristolochic acid and reduce its kidney toxicity. *Kidney Int* 2008;73(11):1231–9.

TABLE 49.3 Herbal supplements with that may affect chronic dialysis patients.

Supplement	References	Claimed benefits	Risks/side effects/drug interactions	Kidney effects	Other
Garlic ( <i>Allium sativum</i> )	ADA Dietary Supplements, Natural Medicines Database, Banerjee et al. [22]	Reduces cholesterol, reduces blood pressure, treats <i>Helicobacter pylori</i> infection, treats diarrhea, prevents cancer, treats diabetes, immune system stimulation, reduces blood pressure	May increase bleeding time, should be used with caution before surgery because of anti-aggregation effects, especially with warfarin, ginger, ginkgo. Decreases cytochrome P450 enzyme substrates: cyclosporine, some calcium channel blockers. Decreases efficacy of antiretrovirals especially protease inhibitors: do not combine. In rats, high doses have been shown to be toxic perhaps due to prooxidant effects, or inhibition of alkaline phosphatase or alcohol dehydrogenase. High doses of garlic homogenate can change the cellular architecture of kidneys in rats. May cause GI distress	Shown to decrease lipid peroxidation in heart, kidney, and liver in rats fed with red garlic homogenate. May lower blood lipids, particularly oxidized LDL through enhanced nitric oxide production. Some animal studies have indicated that garlic is renoprotective when administered before known nephrotoxins	Many types of garlic preparations; they have different properties and efficacy because of different chemical compositions from processing
St. John's wort ( <i>Hypericum perforatum</i> )	ADA Dietary Supplements, Shibayama et al. [23], Natural Medicines Database	Reduces depression, increases well-being. Does seem to have positive effects similar in scope to antidepressants in patients with moderate depression. Mixed results in major depression	GI symptoms, dizziness, headache, hypoglycemia, photosensitivity are side effects. Should not be used by individuals with Alzheimer's. Abrupt discontinuation may cause anxiety, headaches, and insomnia. Causes hypotension in anesthesia. Additive effects with antidepressant drugs may be dangerous. Decreases effectiveness of contraceptives, protease inhibitors, digoxin, antiepileptics, antipsychotics, immunosuppressives, and anticoagulants. Does not combine with drugs metabolized through the cytochrome P450 pathway, including	Pretreatment with St. John's wort has been shown to reduce cisplatin nephrotoxicity in rats with normal baseline kidney function. How this translates to humans/CKD is unclear	Multiple reports of organ transplant rejection after cyclosporine + St. John's wort

(Continued)

TABLE 49.3 (Continued)

Supplement	References	Claimed benefits	Risks/side effects/drug interactions	Kidney effects	Other
			beta-blockers, antiinflammatories, also does not combine with phenobarbital, phenytoin (speeds metabolism of both, decreases seizure control) and narcotics		
Ginseng ( <i>Panax ginseng</i> , <i>Panax japonicus</i> , <i>Panax quinquefolius</i> , <i>Eleutherococcus senticosus</i> ) active compound is saponins ginsenosides	ADA Dietary Supplements, Natural Medicines Database, Liao et al. [24], Kim et al. [25], Roemheld-Hamm and Dahl [26]	Improves exercise, QOL, energy, mood, sexual function, helps control blood glucose levels	Extremely high doses 3 g root per day (or 600 mg extract) may cause hypertension, edema, so lower doses are safe for up to 4 weeks. <i>E. senticosus</i> (Siberian ginseng) is contraindicated for HTN. Changes blood coagulation, unclear if inhibits or encourages platelet aggregation but does not combine with warfarin. Interacts with corticosteroids, digoxin, furosemide, diabetes medications (due to blood glucose-lowering effects). Has mild hormone effects, can interfere with contraceptives, hormone therapy, avoid if history of estrogen-related cancers. Some reports of insomnia, perhaps due to stimulant effects	Study in rats with streptozotocin-induced diabetes showed lower blood glucose levels and less diabetic nephropathy (lower creatinine and urinary protein levels compared to controls) when fed heat-treated American ginseng. The case report of an 83-year female with renal insufficiency experiencing brachycardia and increased digoxin levels after ingestion of ginseng for approximately 1 month. Ginseng is known to increase digoxin, perhaps due to their similar structures. The kidneys are the main organ responsible for digoxin removal	Reports of contaminated ginseng products: 8/20 had high levels of pesticides, 2/20 had lead levels, and 7/20 had low levels of ginsenosides (active compounds)
Ginkgo biloba	ADA Dietary Supplements, Kim et al. [27], Natural Medicines Database	Improves memory and circulation	May cause GI upset, including diarrhea, nausea vomiting at high doses. Interacts with seizure medications, can decrease clotting when on anticoagulant drugs but may also increase the risk of intracranial bleeding. Interacts with certain antidepressants (buspirone, fluoxetine, St. John's wort) to create hypomania. Reduces the efficacy of thiazide diuretics, should not be combined with	Study in 33 PD patients showed that ginkgo biloba extract (150 mg/d for 8 weeks) decreased D-dimer levels compared to the control group. No changes in bleeding time, albumin, or CRP were noted; however, one patient dropped out due to GI side effects	Ginkgo seeds are poisonous, leaves are used

(Continued)

TABLE 49.3 (Continued)

Supplement	References	Claimed benefits	Risks/side effects/drug interactions	Kidney effects	Other
			anticonvulsants as the ginkgo toxin can cause seizures, can also change the action of diabetes drugs, can cause spontaneous bleeding when combined with ibuprofen		
Melatonin	ADA Dietary Supplements, Herrera et al. [28], Koch et al. [29,30], Natural Medicines Database	Regulates circadian rhythms, including in jet lag, helps with migraines, reduces cancer risk, and enhances sex drive	Long-term effects unknown, seems safe in short term. Can interfere with immunosuppressive drugs and other sleep medications. Use caution when combining with antidiabetic drugs, anticoagulant drugs, central nervous system depressants (additive sedative effects)	Nine new HD patients receiving IV iron, and ruHEPP had increased oxidative stress compared to matched controls but those who were administered oral melatonin (0.29 mg/kg) 1 h prior to EPO had lower measures of oxidative stress compared to those who received to placebo before EPO (lower plasma malondialdehyde, RBC glutathione, and catalase). In 20 daytime HD patients, crossover design 3 mg melatonin administered at 10 p.m. for 6 weeks improved subjective and objective measures of sleep time and quality and nights of dialysis and nondialysis days	
CoQ10 (ubiquinone)	ADA Dietary Supplements, Shojaei et al. [31]	Antioxidant effects claimed: improve health in heart disease, HTN, exercise, cancer, prevent migraines	GI distress, including appetite suppression, vomiting, diarrhea, nausea, may occur. May reduce the efficacy of warfarin and have an additive effect with antihypertensives	CoQ10 when administered alone or in combination with carnitine for 3 months lowered lipoprotein(a) levels in HD patients on statins compared to those on statins only. No adverse effects were noted	Smoking, HMG-CoA reductase drugs may deplete body stores. B-6 is required for endogenous synthesis
Noni juice (from <i>Morinda citrifolia</i> )	ADA Dietary Supplements, Natural Medicines Database	Prevents cancer, increases immunity, reduces BP, reduces cholesterol levels, pain relief, controls diabetes	Potassium content similar to orange juice, risk of hyperkalemia; should not be combined with ACE inhibitors, ARBS, and potassium-sparing diuretics. May also reduce efficacy of warfarin, reports of hepatotoxicity from Noni juice consumption, reversed with the termination of consumption		
<i>Echinacea</i> ( <i>Echinacea angustifolia</i> , <i>Echinacea pallida</i> , <i>Echinacea purpurea</i> )	ADA Dietary Supplements, Natural Medicines Database	Boosts immune function, protects against colds and URI, UTIs, yeast infections	Can cause fever, GI upset, taste alterations, dry mouth, headache, dizziness, insomnia. Patients with grass allergies should use with caution as anaphylaxis has been reported. Decreases efficacy of immunosuppressants, should be avoided in patients with autoimmune diseases, also not to be combined with hepatotoxic medications. Can increase plasma levels of caffeine by 30% due to inhibition of cytochrome P450, should avoid with other cytochrome P450 substrate drugs		
Glucosamine	ADA Dietary Supplements, Natural Medicines Database	Reduces pain in joints from osteoarthritis by protecting and producing collagen, and other cartilage components. Mixed results: may be safer than others, but as effective as NSAIDS, other studies show no results	May impact blood glucose control, should monitor patients with DM. Patients with shellfish allergy should not consume. Additive effect with warfarin, should not be combined	Anecdotal reports of induced renal toxicity	

(Continued)

TABLE 49.3 (Continued)

Supplement	References	Claimed benefits	Risks/side effects/drug interactions	Kidney effects	Other
Ginger ( <i>Zingiber officinale</i> )	ADA Dietary Supplements, Natural Medicines Database, Onwuka et al. [32], Shanmugam et al. [33]	Antinausea (pregnancy, chemo, postsurgery), loss of appetite, treats migraines	May increase the effect of anticoagulants and glucose-lowering drugs (may increase blood glucose). May have additive effect with calcium channel blockers	Animal studies indicate that it is a protective antioxidant compound against oxidative and nephrotoxic agents, including cadmium, with statistically significant decreases in lipid peroxidation and kidney damage (shrinkage) in rats compared to cadmium treated without ginger. It also protects against alcoholic kidney damage, including reversing tubule degeneration at a dose of 100 mg/kg/d ginger extract for 30 days	GRAS status
Soy	Roemheld-Hamm et al. [26], Imani et al. [34], Siefker and DiSilvestro [35]	Menopause symptoms, hypocholesterolemic, antioxidant, antiinflammatory properties	May lower coagulation factor IX. Soy isoflavones may be elevated in patients on dialysis treatment as they are not well cleared	Studies indicate soy lowers cholesterol and blood pressure	
Flaxseed	ADA Dietary Supplements, Sankaran et al. [36]	Laxative, manages IBS symptoms, improves blood lipids, improves inflammatory symptoms, reduces heart disease risk	Requires extra fluid consumption (150 mL/10 g flaxseed) or risk of impaction; may interact with warfarin therapy. Flaxseed lignins are a phytoestrogen and their effect on hormone-sensitive cancers is unclear, may compete for uptake with exogenous hormones like contraceptives. Flaxseed may have anticoagulant effects (through $n-3$ fatty acid prostaglandin pathway), concerns for surgical bleeding, and additive effects with anticoagulant medications. May increase triglycerides in individuals with hypertriglyceridemia. May have additive effect with glucose-lowering drugs, high	Flaxseed oil–based diets in diabetic rats and mice with PKD have prevented renal injury when initiated early in the disease state, but when initiated later (2 months in PKD rats, similar to stage 3 CKD) renal injury is not ameliorated, but inflammation is reduced	

(Continued)

TABLE 49.3 (Continued)

Supplement	References	Claimed benefits	Risks/side effects/drug interactions	Kidney effects	Other
			fiber content may also inhibit the absorption of other drugs, including furosemide		
Black cohosh ( <i>Cimicifuga racemosa</i> )	ADA Dietary Supplements, Roemheld-Hamm et al. [26]	Reduces premenstrual and postmenopausal symptoms	Although not a hormone, it affects hormones so should be avoided in women with breast cancer or who are pregnant. GI upset may occur, may also cause weight gain, cramping. Long-term use discouraged, may be safe for up to 6 months. Must be avoided in individuals with existing liver disease or who are taking hepatotoxic drugs due to its potential hepatotoxicity (49 reports of hepatotoxicity). May inhibit cytochrome P450, so should be avoided with substrate drugs, one case report of negative effects when combined with Lipitor		
Remifemin is the brand name of standardized extract					
Lutein	ADA Dietary Supplements, Sundl et al. [37]	Treats age-related macular degeneration and cataracts	No data on drug interactions. So far proven safe and effective even with long-term use	PD patients have been found to have lower lutein levels (and other carotenoids) than healthy matched controls and within PD patients lower carotenoid status correlates with higher inflammatory markers. No research on how lutein supplementation affects these parameters	
Milk thistle ( <i>Silybum marianum</i> )	ADA Dietary Supplements, Vessal [38], Natural Medicines Database	Improves liver health, including treating viral hepatitis and alcoholic cirrhosis, improves appetite, is used to manage diabetes	GI upset, including nausea, diarrhea, allergic reactions, may occur. May interact with antiretrovirals, cytochrome P450 metabolized drugs, may speed clearance of statins, diazepam, digoxin, morphine. May chelate iron	Milk thistle extract, fed for 4 weeks at 1.2 mg/kg to streptozotocin-induced diabetic rats lead to lower serum glucose, serum urea, higher eGFR, and lower 24-h urinary protein than streptomycin diabetic rats not receiving the supplement and did not affect the parameters of control (nondiabetic) rats who received the supplement. The silymarin itself (100 mg/kg) improved parameters in the diabetic rats but was not statistically significant. It is suggested that the mechanism is through ROS scavenging	
Saw palmetto ( <i>Serenoa repens</i> )	ADA Dietary Supplements, Natural Medicines Database	Improves enlarged prostate, prevents prostate cancer, prevents male alopecia, diuretic, antiinflammatory	Anticoagulant, should be discontinued before surgery. Should not be mixed with other anticoagulant medications. May interact with hormone medications through antiestrogenic effects		

ARBS, angiotension receptor blockers; CKD, Chronic kidney disease; CRP, C-reactive protein; eGFR, estimated glomerular filtration rate; EPO, erythropoietin; GI, gastrointestinal; GRAS, generally regarded as safe; HD, hemodialysis; IBS, inflammatory bowel syndrome; IV, intravenous; LDL, low-density lipoprotein; NSAIDS, nonsteroidal anti-inflammatory drugs; PD, peritoneal dialysis; PKD, polycystic kidney disease; rHuEPO, recombinant human erythropoietin; ROS, reactive oxygen species; URI, upper respiratory infection; UTI, urinary tract infection; QOL, quality of life.

wort was effective in reducing mild or moderate depression. To be included in this analysis the study had to meet the following criteria: (1) randomized and double-blind; (2) patients with depressive disorders; (3) compared extracts of St. John's wort with placebo or standard antidepressants; and finally, (4) clinical outcomes such as scales assessing depressive

symptoms. A total of 37 clinical trials were ultimately included in the metaanalysis. The St. John's wort was more effective in moderate or mild depression than in severe depression. The relative risk for the reduction of depression symptoms by St. John's wort from six larger trials was 1.71 (95% CI, 1.40–2.09) and from five smaller trials was 6.13 (95% CI, 3.63–10.38) [39].

The primary active ingredients in St. John's wort are hypericin and pseudohypericin. The mechanism of both hypericin and pseudohypericin related to improving mild and moderate depression is the inhibition of reuptake of serotonin into the central nervous system [40]. It may be hypothesized that depression is caused by a reduction in the functional activity of monoamines such as the centrally acting neurotransmitters: serotonin, dopamine, and norepinephrine. Inhibition of the reuptake of serotonin by St. John's wort results in increased concentration of serotonin in specific nerve synapse and thus improves functionality of serotonin.

Bioavailability of St. John's wort is poor; it is estimated at 14% for hypericin and 21% for pseudohypericin [40]. Excretions of these compounds in St. John's wort are through the kidneys, and the half-life is 25–26.5 hours for hypericin and 16–36 hours for pseudohypericin [41].

In the non-CKD population an effective dose consists of 300–900 mg of the plant extract per day due to the variability in concentration from 0.2% to 2.5% of hypericin [41]. However, no data were found concerning the safe dose for CKD patients. It is possible that in end-stage renal disease patients, St. John's wort compounds may accumulate in the body since the typical route of excretion is no longer available, but there are no data to confirm this possibility.

Side effects in people taking St. John's wort are rare and may include photosensitivity. However, drug interactions are a concern. St. John's wort may interfere with the action of monoamine oxidase inhibitors and selective serotonin reuptake inhibitors; it may antagonize reserpine and reduce serum concentrations of cyclosporine, indinavir, and possibly other drugs used to control HIV infection. Additionally, the active compounds may reduce estrogen concentrations from oral contraceptives, decrease the efficacy of digoxin, irinotecan, other cancer treatment drugs, and seizure control drugs, such as Dilantin and phenobarbital. Finally, warfarin and related anticoagulants may be affected by St. John's wort [21]. Due to the effects on cyclosporine, transplant patients must be monitored closely for use of this herb, and doses of either the cyclosporine or St. John's wort may need to be altered to prevent risk of rejection.

### Garlic: *Allium sativum*

The reported benefits of garlic are on such risk factors for cardiovascular disease as reduced serum lipid concentrations [total cholesterol, low-density lipoprotein (LDL), and triglycerides] and blood pressure, increased fibrinolytic activity, antibiotic properties, enhanced activity of natural killer cells, and lengthened clotting time [21,40]. In the non-CKD population, randomized clinical trials demonstrate the effectiveness of garlic as a hypocholesterolemic supplement.

Kannar et al. [42] conducted a 12-week, double-blind, randomized clinical trial in patients with hypercholesterolemia. All patients received dietary counseling on a low-fat intake and then the treatment group received an enteric coated garlic powder tablet, while the other arm received a placebo. The treatment tablet contained 9.6 mg of allicin. The treatment group ( $n = 22$ ) had a significant reduction in total cholesterol ( $-0.36$  mmol/L) and LDL ( $-0.44$  mmol/L), while the placebo group did not change significantly.

A metaanalysis was conducted by Jepson et al. [43] to assess the effects of garlic for the treatment of peripheral arterial occlusive disease; unfortunately, only one study met the inclusion criteria, and it was small without statistically significant results. No clinical trials testing the efficacy or safety of garlic in dialysis patients were found.

Due to the effects on clotting time, patients who are on anticoagulant medications such as heparin, Coumadin, or even aspirin may be at risk. Additionally, patients who are scheduled for surgery should be advised to withhold the consumption of garlic prior to the procedure [44].

The active ingredient in garlic is allicin, an organic disulfide, which is formed when the substance, alliin, in garlic cloves is crushed or pressed. Crushing the garlic clove releases the enzyme alliinase that converts alliin into allicin. When interpreting data on garlic as an intervention, it is important to know the amount of active allicin in the garlic preparation. Allicin is metabolized in the liver to an inactive compound and eliminated. Since garlic is metabolized and eliminated by the liver, it may be safe for CKD patients to consume garlic for cholesterol and blood pressure as long as increased time for blood clotting is monitored (see Fig. 49.2).

The mechanism of garlic as a lipid-lowering agent is not well understood; however, it is hypothesized that allicin reduces the activity of HMG-CoA reductase. HMG-CoA reductase is an enzyme in the initial step of

FIGURE 49.2 Formation of active compound, allicin, in garlic cloves.

cholesterol synthesis; therefore allicin may reduce endogenously manufactured cholesterol.

### Ginkgo

Ginkgo biloba has been used to improve or stabilize mental function, enhance memory, and improve cerebral and peripheral disease. Ginkgo biloba was tested in 66 chronic peritoneal dialysis patients by Kim et al. [27] to determine whether the herb improves hemostatic factors and inflammation. The patients were randomized to either a control group or to receive ginkgo biloba, 160 mg/d, for 8 weeks. At the baseline of the study, there were no statistically significant differences between the control and ginkgo biloba groups for age, gender ratio, presence of diabetes and cardiovascular disease, and dialysis vintage. At the end of 8 weeks, the only parameters that changed significantly were the plasma D-dimer concentrations, which are an index of fibrin turnover and intravascular thrombogenesis. Plasma D-dimer levels decreased from  $0.92 \pm \text{SD } 0.59$  to  $0.75 \pm 0.48 \mu\text{g/mL}$  ( $P < .05$ ) in the ginkgo-treated group but did not change significantly in the control group. It may be that an active component of ginkgo biloba affects coagulation factors and thus the D-dimer levels.

Since ginkgo biloba may cause extended clotting times, patients undergoing surgical procedures or using anticoagulating medications, such as heparin, should discontinue the use of ginkgo biloba or at least have their coagulation parameters closely monitored. Other potential side effects of ginkgo are gastrointestinal complaints such as constipation, diarrhea, nausea, and abdominal pain, headache, and allergic skin reactions [44].

### Soy

Soy contains high amounts of isoflavones and phytoestrogens. Women with end stage renal disease (ESRD) may be particularly interested in soy products due to its reported effects on reducing menopausal symptoms, such as hot flashes. The phytoestrogens in soy products are thought to be responsible for reducing the menopausal symptoms in addition to their potentially beneficial effects on osteoporosis and cardiovascular disease prevention. Furthermore, are sufficient data demonstrating efficacy of soy food products for cholesterol reduction to warrant statements indicating this effect on food labels.

Recently, a few small trials have been published on soy supplementation in chronic dialysis patients. An unblinded, randomized trial was conducted [34] on the effect of soy on plasma-coagulating factors. This study included 36 chronic peritoneal dialysis patients (18 on soy and 18 as control) who were followed for 8 weeks. The soy group received 28-g packets of raw, textured soy flour providing 14 g of soy protein, and 233 mg of phosphorus. Patients were not included in the study if their baseline serum phosphorus was greater than 5.5 mg/dL. At

baseline, there were no significant differences in any demographic characteristics except for supplemental vitamin B<sub>12</sub> intake (more patients were taking vitamin B<sub>12</sub> in the soy group). At the end of the 8-week period, there was no statistically significant difference in serum phosphorus, as might be expected [soy group  $3.5 \pm 1.0 \text{ mg/dL}$  (mean  $\pm$  SD) vs control  $3.7 \pm 0.9 \text{ mg/dL}$ ]. However, there was a significant decrease in plasma coagulation factor IX (baseline soy group  $135\% \pm 33.5\%$  activity vs 8-week  $112.5\% \pm 32\%$  activity). This decrease in plasma coagulation factor IX may constitute a risk factor for patients undergoing chronic dialysis, especially if they are receiving other anticoagulating medications or herbal supplements.

Another small trial, this one in hemodialysis patients, used soy verses whey protein and tested the safety and efficacy of these different proteins on serum oxidized LDL concentrations. The study randomized 17 hemodialysis patients to receive either soy ( $n = 7$  patients, 25-g protein and 52-mg flavones) or whey ( $n = 9$  patients) for 4 weeks. There were no statistically significant changes in laboratory values between pre and postintervention in either group, except for serum creatinine that significantly decreased in the whey group. A significant difference in the mean change in serum oxidized LDL concentrations was found between the groups, with the serum levels in the soy group decreasing by 31.02%, and the levels in the whey group increasing by 11.12% ( $P < .05$ ) [35].

In 2016 a systematic review and metaanalysis was published on the effect of soy protein containing isoflavones on clinical outcomes in CKD patients. There were 12 studies with 280 patients included in the final analysis that comprised both nondialyzed advanced CKD and chronic dialysis patients. The analysis indicated that the intake of soy protein was associated with a statistically significant reduction in serum creatinine, phosphorus, and C-reactive protein, and in proteinuria in the advanced CKD patients. No changes with the intake of soy protein were detected in the chronic dialysis patients; however, when the two groups of nondialyzed CKD and chronic dialysis patients were pooled, a significant decrease was found in serum urea nitrogen in the groups ingesting soy protein [45].

From these small studies and the more recent meta-analysis in predialysis and dialysis patients, soy use appears to have some efficacy, and in predialysis patients, it appears to have a lower risk of side effects. However, similar to the other herbal products, soy may interfere with coagulation factors. Thus careful monitoring of clotting parameters would be warranted in patients consuming high amounts of soy.

### Kava kava

Kava extracts are derived from the rhizomes of a perennial shrub in the South Pacific Islands. The term

kava comes from both the kava plant and the kava extracts [46] and is typically consumed as either a capsule or tablet containing either ethanolic or acetonic extracts. The active ingredients in kava are kavapyrones, also known as kavalactones, which have psychoactive properties. In the Western populations, kava has been used to treat anxiety. A randomized, double-blind crossover study was published in 2009 on the aqueous extract of kava [47]. The 60 adult subjects had 1 month of elevated, generalized anxiety ( $>10$  on the Beck Anxiety Inventory) prior to enrolling in the study. During the treatment phase of the study (length = 1 week) the patients received five tablets of kava per day, each containing 50 mg of kavalactones. The pooled analysis across phases (using differences from pretreatment scores) demonstrated a significant effect across phases in favor of kava [ $F(1,35) = 26.18$ ;  $P < .0001$ ] and a strong effect size [47].

It is important to note that the previous clinical trial used the aqueous extract form of kava, and the duration of the intervention period was only 1 week. Teschke et al. [48] described several reports of the hepatic toxicity of the ethanolic or acetonic extracts of kava. In an analysis of kava kava [49], when quantitative tools for assessing causality were used, the data strongly supported a cause and effect relationship between the kava consumed and hepatotoxicity.

Therefore, although aqueous kava extract does appear to relieve anxiety in healthy adults, health-care workers should be aware, and patients must be cautioned that evidence strongly indicates an association between intake of kava extract and hepatotoxicity. Moreover, there are no clinical trials involving the effects of kava on patients with CKD.

## Kidney transplantation

Patients who have received a kidney transplant need to be particularly aware of herbal supplements that are metabolized by the cytochrome P450 enzymatic system. The P450 system metabolizes some of the antirejection medications prescribed posttransplant, such as cyclosporine. Therefore the ingestion of herbals that are processed by the same enzymatic system may result in decreased drug concentrations and thus put the patient at increased risk of rejection. Some examples of herbal supplements that are acted on by the cytochrome P450 system are St. John's wort, *Echinacea*, and melatonin.

## Clinical implications

As stated in the introduction of this chapter, surveys have been conducted indicating a high use of herbal

supplements in both the general and CKD populations. It is not uncommon for patients to withhold information on their use of herbal supplements from health-care providers. Given the potential for contaminants and herb-to-drug or herb-to-herb interactions, it is imperative that health-care providers know what patients are consuming so that they can educate patients on potential risks and monitor patients more effectively. At present, there are no validated, CKD-specific questionnaires that include information on herbal or other CAM use. Therefore clinicians need to conduct thorough, individualized assessments that include specific questions regarding herbal use by their CKD patients.

In summary, herbal use is probably common in CKD and chronic dialysis patients. Many herbs contain active compounds that may interact with other medications or may have direct negative effects on the health of the patients. There are few studies of the administration of herbs to CKD patients. However, some studies do demonstrate both reasonable safety and some effectiveness in CKD patients; soy is an example. More trials need to be conducted with CKD patients to assure safety and determine the effectiveness of the most commonly used herbals.

# Drug–nutrient interactions in renal failure

Raimund Hirschberg<sup>1,2</sup>

<sup>1</sup>David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA, United States <sup>2</sup>The Lundquist Institute, Torrance, CA, United States

## Introduction

Foods and prescribed or over-the-counter medicines can interact in multiple ways. Such interactions may result in reduced or increased drug effects or in (often subtle) nutritional deficiencies. Drug efficacy may be reduced due to food-induced delayed or decreased absorption from the gastrointestinal tract. Diet or nutrients may induce or inhibit drug-metabolizing enzymes and increase or decrease the rate of metabolism of a given drug; they may also modify the first-pass effect. The rate of excretion of the drug or of active or toxic metabolites may also be altered by dietary effects.

The most commonly observed drug–food interaction is altered drug absorption from the gastrointestinal tract, usually a decrease in the rate of absorption. Less commonly, the drug absorption rate may be increased if taken concurrently with foods. Drugs can also induce certain specific nutrient deficiencies particularly for vitamins and minerals.

In patients with chronic kidney disease (CKD) or end-stage renal disease (ESRD), drug–nutrient interactions may lead to overt nutritional deficiencies particularly when the general nutritional status is poor or there are specific, obvious, or subclinical nutritional deficiencies. This chapter will focus on interactions between drugs typically prescribed to renal patients and foods, food supplements, and some herbal compounds.

## Effect of food intake on drug absorption

The intestinal absorption of many drugs is slowed when administered concurrently with food, either because of delayed gastric emptying or because of dilution of the drug in the intestinal contents. Some medications, such as central  $\alpha_2$ -adrenergic drugs, can reduce

gastrointestinal motility and delay the emptying of the stomach and, hence, increase oral–fecal transit time [1]. In contrast, calcium channel blockers do not appear to affect gastrointestinal motility [2]. Table 50.1 lists several drugs that may be prescribed to patients with CKD and which may interfere with the gastric emptying rate. Table 50.2 lists drugs that are absorbed more slowly when given concurrently with meals. To optimize drug absorption, these medicines should be given 1 hour before or 2 hours after meals. However, there are a few commonly administered oral medicines that will undergo more effective absorption when administered with foods (Table 50.3). These include commonly used antihypertensives (diltiazem, felodipine, isradipine, labetalol, metoprolol, and propranolol). In most circumstances the food-dependent increase in drug absorption may enhance drug efficacy. However, serious toxic side effects may arise, such as when lithium or cyclosporine is given with foods.

Dietary contents can also reduce gastrointestinal drug uptake by inhibiting organic acid transport proteins (OATPs). Naringin and flavonoids in fruits, fruit juices, and vegetables such as grapefruit and orange juice have been shown to inhibit OATP1A2 [4]. The uptake of drugs that are transported by this protein (fexofenadine, L-thyroxine, atenolol, and ciprofloxacin) can be reduced by as much as 50% [4]. Etoposide absorption is also substantially reduced by grapefruit juice [5].

Subclinical or overt iron deficiency is commonly observed in patients with advanced CKD or ESRD. Low or empty iron stores may be caused by reduced nutrient and, hence, iron intakes as well as subtle iron losses. Iron deficiency is the most common reason for resistance to erythropoietin and other erythropoiesis-stimulating agents (ESAs) in patients with renal failure. Experimental studies have shown that administration of

Diltiazem	Propranolol
Etretinate	Quinidine
Famotidine	Sertraline
Felodipine	Ticlopidine

the phosphate binder calcium carbonate (CaCO<sub>3</sub>) with foods reduces the bioavailability of iron from oral iron sulfate [6]. Apparently, in the presence of calcium, iron is taken up normally into the gut mucosa, but the transfer through mucosal cytoplasm and/or basolateral membranes is reduced. This interaction is prevented by intravenous iron administration.

Roux-en-Y gastric bypass is the most common bariatric procedure for the surgical treatment of severe obesity. It results in a >90% reduction in gastric volume and in reduced functional length of the small bowel with numerous potential nutritional consequences. This may affect drug absorptions and intralumen drug–nutrient interactions.

## Effects of nutrients on drug metabolism

### Dietary protein and lipids

The hepatic clearance of some drugs is reduced in renal failure [7]. Drugs that are metabolized by oxidation, conjugation, or both processes may be predisposed to decreased hepatic clearance in CKD. High-protein diets can raise the activity of drugs that are metabolized through cytochrome P-450-dependent mixed function oxygenases. High-protein diets accelerate the metabolic clearance of some drugs such as theophylline and propranolol by about 30%–60% compared to low-protein diets [8].

Low-protein diets also reduce the activity of xanthine oxidase [9] and increase the plasma levels of allopurinol and oxipurinol. Since oxipurinol accounts for some of the adverse effects of allopurinol, the concurrent prescription of low-protein diets and allopurinol may

increase the likelihood of allopurinol toxicity [9]. The prescription of low-protein diets to patients with CKD may also reduce the sulfate conjugation of some drugs, although clinical studies directly examining this question in patients or normal subjects are lacking. Drug sulfation depends on the availability of sulfur-containing amino acids and the possible release of sulfur in the gut by the action of intestinal sulfatases.

### Cruciferous vegetables and drug metabolism

Drug metabolism can be affected by other compounds derived from certain foods. For example, various indoles that originate from cruciferous vegetables, such as cabbage and Brussels sprouts, enhance oxidation and increase the metabolic clearance rate of medicines. Such foods also may enhance drug glucuronidation in healthy subjects, for example, for acetaminophen [10]. Diet-derived compounds may affect the activity of the P-450 enzyme species by the competitive inhibition of the P-450-dependent monooxygenase system [11]. Indole-3-carbinol and related compounds that are present in cruciferous vegetables, particularly Brussels sprouts, are potent inducers of the intestinal P-450 IA1 (CYP1A1) and hepatic CYP1A1 and CYP1A2 isoenzymes [12].

### Nutrients and cytochrome P-450-dependent drug metabolism

Increased dietary protein augments hepatic microsomal cytochrome P-450 content probably through tryptophan and sulfur amino acids [13]. In contrast the activity of this enzyme system is reduced by low-protein, high-carbohydrate or fat diets, flavonoids (i.e., contained in citrus fruits and some vegetables), large doses of riboflavin, and possibly during total parenteral nutrition. The cytochrome P-450IIE1 (CYP2E1) isoenzyme is induced by dietary lipids [14]. This isoenzyme participates in the metabolism of acetaminophen, enflurane, and halothane [11]. Moreover, the CYP2E1 isoenzyme is also activated by fasting as well as by thiamine deficiency [14]. Several other alterations in the micronutrient status can affect the oxidative metabolism of drugs (Table 50.4).

Large doses of vitamin C given as nutritional supplements to patients without ascorbic acid deficiency may increase the rate of oxidative drug metabolism. High vitamin C intakes can also reduce the rate of sulfate conjugation of drugs, such as acetaminophen, by competing for the available sulfate. Dietary supplementation with large doses of pyridoxine may increase the metabolism and decrease the therapeutic efficacy of levodopa, since this vitamin is a cofactor for the dopa decarboxylase [15].

TABLE 50.4 Effects of micronutrients on oxidative drug metabolism [11].

Vitamin A deficiency ↓ P-450	
	↓ Metabolism of aminopyrine, Coumadin
Vitamin A, high dose	↑ Metabolism of Coumadin
Niacin deficiency	↓ Metabolism of anesthetics
Riboflavin deficiency	↓ NADPH:P-450 reductase

Zinc deficiency	↓ Phenobarbital and aminopyrine metabolism

### Cytochrome P-450 isoenzyme CYP3A4 activity, citrus juice compounds, and St. John's wort

Many drugs are metabolized through the cytochrome P-450 isoenzyme CYP3A4, including those used in patients with renal diseases. Some estimates suggest that CYP3A4 is involved in the metabolism of as much as half of all marketed drugs [16]. It is the broad substrate affinity that renders this isoenzyme so important as well as susceptible to activity modifications by nutrients. A few drugs utilize CYP3A4 for activation from the pro-drug to the active metabolite such as clopidogrel.

This isoenzyme is expressed in liver microsomes where it contributes to drug metabolism and in the enterocyte microsomes of the small intestines where it can reduce bioavailability of substrate drugs due to first-pass effect. Compounds present in citrus juice inhibit CYP3A4, and St. John's wort (extract of *Hypericum perforatum*) induces CYP3A4 levels and activity. Flavonoids, such as naringin, are present in rather large amounts in citrus fruits, citrus juices, and some vegetables [17]. The related aglycone, naringenin, is readily formed in humans from its precursor and, like other flavonoids, inhibits the CYP3A4. A virtually complete list of the content of different flavonoids in various foods is maintained by the US Department of Agriculture and available online [17]. Grapefruit juice which is perhaps the food most potently inhibiting CYP3A4 not only contains naringenin but also psoralen derivative and other flavonoids that are also thought to inhibit this isoenzyme. Many different flavonoids can severely inhibit CYP3A4 (as much as 100% in vitro). These compounds are also found in other citrus juices and fruits, fennel,

bell pepper, celery, carrots, other foods, as well as *Ginkgo biloba* [17,18]. In clinical studies, in normal subjects naringin inhibits the metabolism of the CYP3A4 substrate nisoldipine only moderately giving rise to the importance of other compounds in grapefruit juice as inhibitors of this cytochrome P-450 isoenzyme [19]. Although the effect of these grapefruit juice compounds on CYP3A4 may be clinically more important, they also tend to inhibit several other cytochrome P-450 isoenzymes such as CYP1A2, CYP2C9, CYP2C19, and CYP2D6 [18].

CYP3A4 is present in relatively large concentrations in the wall of the small intestine where it contributes to the first-pass metabolism of several drugs limiting the amount of active drug that reaches the blood stream. The inhibition of CYP3A4 by compounds in grapefruit juice and other citrus fruit juices is clinically important since this isoenzyme plays a major role in the metabolism of drugs that are commonly used in patients with CKD or ESRD. These include cyclosporine A, the dihydropyridine calcium channel blockers nifedipine, nimodipine, felodipine, nitrendipine, and nisoldipine; the calcium channel blocker verapamil; saquinavir; diazepam, midazolam, and triazolam; terfenadine and lovastatin, as well as the hepatitis C direct-acting antivirals daclatasvir, simeprevir, and telaprevir (Table 50.5) [19,20]. The bioavailability of these drugs is increased by coadministration with grapefruit juice and, perhaps, even more so in subjects consuming large amounts of citrus juices chronically (Table 50.5). For example, ingestion of diazepam, 5 mg, with 250 mL of grapefruit juice as compared to water increases the diazepam area-under-the-curve 3.2-fold [21]. The drug–nutrient interaction between compounds in citrus juices and dihydropyridine calcium channel blockers has significant clinical implications. First, the increased plasma levels of the drugs may raise the incidence of adverse effects. Second, in hypertensive patients treated with dihydropyridines, sporadic concomitant ingestion of grapefruit juice may cause symptomatic hypotension. Third, the combination of a dihydropyridine antihypertensive with grapefruit juice can increase the therapeutic efficacy causing hypotension as has been illustrated in a published case report [22]. There are several other compounds (mainly polyphenols) in commonly eaten foods that inhibit CYP3A4. These include but are not limited to tannic acid (pomegranate), flavonoles (chocolate), and phenolic acid (coffee) and are also demonstrated in the following case discussion.

### Case discussion

A 45-year-old obese male lawyer with a history of primary hypertension is followed in a nephrologist's office for CKD3b secondary to hypertensive nephro-arteriolar sclerosis. He also has other cardiovascular risk factors, including hypercholesterolemia and a BMI of 32 kg/m<sup>2</sup>.

Continued

You recommended several lifestyle changes that the patient has all implemented, including reduced calorie and fat intake and more exercise. The patient has taken up mountain biking which he does on most days.

On his most recent visit 2 weeks ago, he was feeling well. He had lost 3 kg of body weight during the preceding 6 weeks. His blood pressure was 119/76 mmHg with a heart rate of 72 bpm. The remainder of his physical examination was normal except for central obesity. The patient was stable on furosemide, 20 mg; atenolol, 50 mg; and enalapril, 20 mg daily. A complete blood count, Na, K, Cl, bicarbonate, calcium, and phosphorus serum levels were normal. Blood urea nitrogen (BUN) was 33 mg/dL, serum creatinine was 1.9 mg/dL, and LDL-cholesterol was 149 mg/dL. A dipstick urinalysis showed 1+ protein (30 mg/dL) but no blood. The patient was started on simvastatin, 40 mg nightly.

Now the nephrologist is called by the emergency room of the regional hospital to see the patient who had just been admitted for "total body pain." He did not have any accident. The pain started about 36 h ago suddenly after a strenuous mountain bike ride. He also noticed much reduced urine output and dark brown urine. On further questioning the patient reveals that he drank large amounts of orange juice during and after the bike ride. Physical findings were remarkable for severe pain upon palpation of both thighs, both upper arms and shoulders. Pertinent laboratory findings include K 6.1 mmol/L; BUN 41 mg/dL; creatinine 7.1 mg/dL; and creatine kinase activity (CK) 69,000 U/L; dipstick urinalysis shows strong blood and protein, and a urinary sediment is positive for brown granular casts but negative for blood cells. The ECG is normal except for signs of left cardiac hypertrophy.

The (obvious) diagnosis in this patient is oliguric acute kidney injury (AKI) secondary to rhabdomyolysis with severe hyperkalemia. The patient is started emergently on hemodialysis and simvastatin is discontinued. After 6 days of daily hemodialysis, his diuresis normalizes. The predialysis creatinine remains stable below 2.5 mg/dL and the pain disappears.

The cause of this patient's rhabdomyolysis is muscle injury from heavy exercise and simvastatin toxicity which, in turn, was caused by an increase in drug exposure from (transient) inhibition of CYP3A4 activity by compounds in the orange juice of which he drank large amounts during the bike ride. The patient should be advised to avoid orange, grapefruit, and citrus juices (except modest amounts) and he should be switched to either pravastatin or rosuvastatin both of which are not metabolized by CYP3A4.

St. John's wort, an over-the-counter herbal folk drug commonly used for mood elevation and as antidepressant, reduces the bioavailability of many drugs due to its induction of CYP3A4 activity in the liver and the

**TABLE 50.5** Drugs that have greater efficacy with grapefruit (citrus) juice due to the inhibition of CYP3A4.

Antibiotics and antifungals	Most azoles Erythromycin Clarithromycin Telithromycin

small intestine (Table 50.6). Other compounds that also induce CYP3A4 include quercetin (broccoli, apples, red wine, onions, green tea, buckwheat flower, and tea; the latter has very high quercetin content; quercetin is also marketed as herbal remedy to “prolong life” and as antioxidant); capsaicin (the “hot” compound in chili pepper); flavone (celery, parsley); and genistein (fava beans, soy beans, and soy bean–derived processed foods) [16].

### Nutrients and urinary excretion of drugs

The deficiency in some trace elements such as iron, zinc, copper, and selenium has been shown to influence the mixed function oxidase system in experimental animals, but for most such elements, studies in humans are not available. Moreover, even marked iron deficiency in man does not appear to affect oxidative drug metabolism.

In CKD the half-life of drugs that are primarily metabolized by hepatic glucuronidation may be prolonged [23].

**TABLE 50.6** Drugs efficacy of which may be reduced by St. John's wort due to the induction of CYP3A4.

Others	Digoxin Omeprazole Phenobarbital Warfarin Levodopa

There is circumstantial evidence that renal insufficiency per se reduces hepatic drug clearance. Although it is possible that fasting, malnutrition, or specific nutrient deficiencies may alter the hepatic glucuronidation of some drugs, the literature at present does not provide clearly supportive data.

The urinary excretion of certain drugs or of bioactive or toxic metabolites does not only depend on the degree of renal failure, that is, reduction in glomerular filtration rate (GFR) or creatinine clearance, but also on urinary pH. In patients with normal renal function and even in patients with moderate or even advanced CKD, urinary pH depends largely on dietary intakes, at least during the postabsorptive period.

A low-protein diet produces more alkaline urine, and conversely, a high-protein diet results in more acidic urine. Drugs or drug metabolites that are weak bases are more efficiently excreted in acidic urine, whereas more alkaline urine will promote the excretion of drugs or metabolites that are weak acids. Foods that potentially acidify the urine include meats, fish, eggs, cheese, bread, cranberries, plums, and prunes. More alkaline urine can be caused by milk, various fruits, and all vegetables except corn and lentils.

### **Interactions of food supplements with drugs**

Patients with advanced CKD and those on maintenance dialysis are often prescribed food supplements, such as vitamins and iron preparations, or potassium and phosphate binders. Specific interactions between certain drugs and these food supplements have been described that may not only reduce the blood levels of the drug but may also reduce the drug efficacy. Thus it may be necessary to separate the timing of the intake of the food supplement from that of the drug. In general, the drug should be taken 1 hour before or 2 hours after the supplement, but in some circumstances this period of time should be even longer (up to 4 hours). For example, oral calcium salts reduce the intestinal absorption of levothyroxine by 30% or more when taken concomitantly or within 2 hours or less. It is recommended to keep 4 hours between the two medications.

Supplemental folic acid decreases the blood levels of phenobarbital [24] and may lead to breakthrough seizures. Pyridoxine (vitamin B<sub>6</sub>) when given in large dosages (400 mg/d) can also reduce the serum levels of phenobarbital, possibly by increasing the activity of pyridoxal phosphate-dependent enzymes. In animal experiments, large doses of pyridoxine reduces the activity of isonicotinic acid against tuberculosis. Pyridoxine appears to form a Schiff base with isonicotinic acid which is then excreted in the urine or removed during dialysis. Concomitant therapy with pyridoxine and L-dopa in patients with Parkinson's disease reduces the efficacy of the latter drug and worsens the disease symptoms.

Excess intake of vitamin E can induce a hemorrhagic state in laboratory animals caused by vitamin K deficiency [25]. Patients on Coumadin therapy are at risk for developing hemorrhages that result from unwarranted further suppression of the vitamin K–dependent clotting factors by concomitant intake of vitamin E. It has been suggested that megadoses of vitamin C (>1 g/d) may lead to vitamin B<sub>12</sub> deficiency apparently by the destruction of vitamin B<sub>12</sub> by vitamin C when they are taken together.

Bioavailability of ciprofloxacin is reduced if the drug is coadministered with aluminum hydroxide-containing

phosphate binders. Aluminum hydroxide as well as magnesium hydroxide reduce the bioavailability of ciprofloxacin by as much as 90% when given concomitantly or within <0.5 hours, and a lesser but still significant reduction occurs when the drug is given within up to 4 hours after the antacid. Similar reductions in the bioavailability occur for other fluoroquinolone antibiotics, such as norfloxacin, ofloxacin, and enoxacin when administered up to 4 hours after intake of aluminum-, magnesium-, or calcium-containing phosphate binders [26]. A significant decrease in the bioavailability of fluoroquinolones was also described by several authors to occur upon coadministration with several oral iron supplement preparations such as ferrous sulfate, fumarate, or gluconate. Calcium-containing phosphate binders or antacids have also been shown to reduce the bioavailability of tetracyclines [27]. Sevelamer does not appear to have such effects on drug bioavailability. The reduction of iron absorption from diet or ferrous sulfate due to coadministration of calcium-containing phosphate binders has been discussed earlier in this chapter.

### **Drug-induced nutritional deficiencies**

Several prescribed or over-the-counter medicines reduce appetite and food intake. In patients with CKD or on maintenance dialysis, this may aggravate an already poor nutritional status and may contribute to frank malnutrition. However, of greater concern are more specific interactions of prescribed drugs with micronutrients, mainly with certain vitamins and minerals.

### **Drug-induced vitamin deficiencies**

Vitamin metabolism and requirements in patients with renal disease and renal failure are described in [Chapter 25](#), Vitamin D in Kidney Disease, and [Chapter 26](#), Vitamin Metabolism and Requirements in Chronic Kidney Disease and Kidney Failure. Current guidelines do not recommend the routine prescription of micronutrient supplementation to patients with CKD1–5D albeit this does not preclude the need for vitamin supplementation in some patients [28]. Thiamine deficiency may be aggravated or caused by chronic alcoholism. The literature, at present, does not suggest that specific short- or long-term drug therapies may cause vitamin B<sub>1</sub> deficiency. However, thiamine deficiency may occur in severely ill patients who undergo parenteral nutrition [29]. Thiamine is a coenzyme for pyruvate dehydrogenase, and thiamine deficiency may cause the acute onset of unexplained,

severe lactic acidosis [29]. Riboflavin deficiency can be caused or aggravated by long-term administration of chlorpromazine or amitriptyline. Pyridoxine deficiency may be caused by long-term treatment with isoniazid. It is recommended that vitamin B<sub>6</sub> supplements (10–15 mg/d) be prescribed for the entire period of time that isoniazid is taken. Vitamin B<sub>6</sub> deficiency may also be caused by hydralazine and penicillamine [15]. High doses of pyridoxine hydrochloride reduce the serum levels of anticonvulsants and may reduce the clinical seizure control. Chronic vitamin B<sub>12</sub> deficiency may develop during long-term treatment with colchicine, metformin, or cimetidine, other H<sub>2</sub>-blockers and proton pump inhibitors, especially if the dietary intake is marginal [30,31].

Several drugs antagonize folic acid and may cause megaloblastic anemia. These include phenytoin, phenobarbital, sulfasalazine, triamterene, trimethoprim, trimetrexate, and methotrexate [32]. On the other hand, folate supplementation may interact with these medicines and reduce their clinical efficacy. Daily dosages of folate of more than 5 mg reduce the plasma levels of phenytoin and phenobarbital and may reduce their therapeutic efficacy. A risk for the development of niacin deficiency may exist when treatment with isoniazid is prescribed. During such treatment, concurrent administration of niacin (100 mg/d) may be advisable. Retinoids and possibly retinol increase the blood cyclosporine levels [33]. Vitamin A supplements should be avoided in renal patients. In addition to Coumadin, there is a number of drugs that can cause vitamin K deficiency and that may induce or enhance severe bleeding. This has been described particularly with the administration of moxalactam, cefotetan, cefamandole, cefoperazone, and other cephalosporins that contain the methylthiotetrazole side chain. Vitamin K supplements should be administered concurrently with these antibiotics [34]. Weaker antivitamin K effects have been shown with tetracycline and cholestyramine. Ingestion of megadoses of vitamin E can cause vitamin K deficiency and should be avoided.

Drug-induced osteomalacia can be due to chronic intake of anticonvulsants, isoniazid and possibly cimetidine. Anticonvulsant therapy with phenytoin, phenobarbital, or carbamazepine results in reduced levels of 24,25-dihydroxyvitamin D<sub>3</sub>, and this may play a role in the anticonvulsant-induced osteomalacia [35]. In patients with CKD, this drug-induced risk for osteomalacia may be additive to the increased risk of renal bone disease. Patients undergoing chronic dialysis therapy are often prescribed 1,25-dihydroxycholecalciferol or analogs. However, in patients with moderate CKD not receiving 1,25-dihydroxycholecalciferol, vitamin D supplements should be given concurrently with the previous drug treatments. Moreover, it is recommended to

prescribe vitamin D supplementation (cholecalciferol or ergocalciferol) to maintain normal 25(OH)-vitamin D levels to patients with CKD1–5D [28].

### Drug-induced mineral and trace element deficiencies

As a rule, the intakes of many minerals such as Na, K, Mg, Ca, and P correlate with the dietary protein intake [36]. Mineral and trace element deficiencies may develop due to poor nutritional intakes, and elderly patients are at greater risk. Mineral depletion can occur due to poor gastrointestinal absorption and/or enhanced renal excretion, the latter mainly in patients with lesser degrees of CKD. Both, reduced absorption and enhanced excretion of minerals can be caused by drug therapy. Potassium, calcium, magnesium, iron, and zinc are the most common minerals that become depleted in patients with CKD. Drug-induced potassium deficiency in patients with CKD most commonly results from diuretic therapy and can be caused by both thiazide and loop diuretics. With diuretic therapy, magnesium deficiency may also develop.

Concurrent intake of aminoglycosides and cephalosporin antibiotics can be interactive and cause potassium (and magnesium) depletion, particularly when intakes of these minerals are low which may occur with the ingestion of low-protein diets. Hypokalemia can also occur with gentamycin toxicity and during treatment with amphotericin B. Potassium deficiency may also be caused by laxative abuse with resulting potassium losses through the gastrointestinal tract. Lithium carbonate and levodopa can contribute to potassium deficiency [37]. Hypokalemia and potassium depletion worsen blood pressure levels in hypertensive patients and may contribute to the thiazide-induced carbohydrate intolerance.

Calcium deficiency can be caused by poor dietary intake, primary malabsorption or vitamin D-deficiency-induced malabsorption, or drug-induced hypercalciuria. Primary calcium malabsorption can result from enteropathy caused by neomycin, colchicine, methotrexate, and corticosteroids. Aluminum and magnesium hydroxide may reduce calcium absorption. Phenytoin and phenobarbital may interfere with vitamin D metabolism as described earlier. Loop diuretics, such as furosemide, torsemide, and ethacrynic acid, can cause hypocalcemia secondary to hypercalciuria. In patients with chronic renal failure, combined treatments with drugs that interfere with calcium metabolism are not uncommon.

Hypercalcemia in patients with CKD may result in soft tissue calcification and nephrocalcinosis that may contribute to the progression of renal disease or may itself cause CKD. The long-term combined intakes of

large amounts of  $\text{CaCO}_3$  and (vitamin D–fortified) milk can lead to severe chronic hypercalcemia and nephrocalcinosis causing CKD, the so-called milk-alkali syndrome [38]. Medullary nephrocalcinosis in this syndrome may also be the cause of CKD. In patients with CKD, hypercalcemia may result from the intake of calcium-containing phosphate binders and/or vitamin D derivatives.

Hyperoxalemia and hyperoxaluria can be caused or aggravated by vitamin C supplementation, even at moderate doses (i.e., 500 mg/d) [39]. Patients who eat relatively large amounts of foods that generate oxalate (e.g., green salads) and take moderate or megadoses of vitamin C have an increased risk to develop hyperoxalemia-associated complications [39].

Zinc deficiency may be caused or worsened by total parenteral nutrition without adequate zinc intake. Administration of penicillamine or corticosteroids has also been associated with zinc deficiency [40]. Zinc depletion causes or contributes to clinical symptoms that are often observed in patients with CKD, such as loss of appetite and altered taste and smell sensation. Loss of taste or smell may lead to reduced food intake and, hence, malnutrition. Aspirin (even at the low dose of 81 mg/d), ibuprofen, and other nonsteroidal antiinflammatory drugs may cause occult gastrointestinal bleeding and contribute to iron losses. Iron depletion and anemia may also be caused by poor food intake or reduced bioavailability from nonheme iron in foods such as due to concomitant calcium-containing phosphate binders. This has been discussed earlier. There are not sufficient data to indicate whether there are important drug interactions with other trace element micronutrients, such as selenium, molybdenum, chromium, manganese, rubidium, and others.

### **Nutrient interactions with some itemized drugs**

#### **Taurine and ACE-inhibitor effects**

The amino acid taurine blocks actions of angiotensin II by inhibiting cellular  $\text{Ca}^{2+}$ -uptake and angiotensin II signaling. In experimental in vitro and in vivo studies, taurine food supplements were found to have renal antifibrogenic effects comparable to those of angiotensin converting enzyme (ACE) inhibitors [41].

Serum and red blood cell taurine levels tend to be lower in diabetics compared to normal subjects, and taurine food supplements can normalize taurine levels [42]. Foods rich in taurine include seafood, particularly crustaceans and molluscs, and lesser amounts are present in beef, pork, and lamb. Taurine-containing food supplements are available over the counter. Whether increased dietary taurine will indeed reduce the

progression of renal disease and/or reduce the cardiovascular mortality in chronic dialysis patients is unknown due to the lack of respective clinical trials. Nevertheless, this may be an example of collaborative, beneficial drug–nutrient interaction.

#### **Hyperuricemia and nontraditional uricosurics**

Purine-rich diets can contribute to hyperuricemia. Asymptomatic hyperuricemia may cause CKD (uric acid nephropathy) or accelerate the rate of progression of CKD [43]. Whether asymptomatic hyperuricemia should be treated with uric acid–lowering agents is controversial [44]. In contrast, symptomatic hyperuricemia (gout, urate nephrolithiasis, urate or uric acid crystalluria, or known uric acid nephropathy) should be treated with uric acid–lowering drugs. Direct-acting uric acid–lowering drugs include allopurinol, febuxostat, and rasburicase. The latter is a human recombinant enzyme protein for intravenous administration and reserved for very severe hyperuricemia such as in the tumor lysis syndrome due to its high cost. In addition, canagliflozin, losartan, and fenofibrate also lower uric acid serum levels through uricosuric effects. It is conceivable that the treatment of patients with severe hyperuricemia with these latter drugs could cause crystalluric AKI but this complication has thus far not been reported. Diuretics, aspirin, cyclosporine A, mycophenolate mofetil, and ACE inhibitors raise serum uric acid levels [45].

### **Nutrient interactions with oral anticoagulants**

Until recently, Coumadin was the mainstay of oral anticoagulation therapy in nonrenal as well as CKD patients. This drug is a prime example of the importance of foods that can interfere with drug actions. This is mainly because of the small therapeutic window between under- and overdose as well as its reduced efficacy by dietary vitamin K intakes. Table 50.7 summarizes commonly consumed foods with relatively high vitamin K content. In contrast the intake of large amounts of vitamin E can cause vitamin K deficiency and increase the bleeding risk in patients taking Coumadin. In addition to several blood coagulation enzymes, some other proteins require vitamin K as a cofactor for their activation by carboxylation. These include proteins with functions in bone and calcium metabolism such as osteocalcin and matrix Gla protein [47]. Hence, warfarin is also a risk factor for osteoporosis and vascular calcifications in ESRD patients.

TABLE 50.7 Common foods with high-phyloquinone (vitamin K<sub>1</sub>) content [46].

Phylloquinone (μg/100 g)	
<b>Vegetables</b>	
Collard greens	440
Spinach	380
Salad greens	315
Broccoli	180
Brussels sprouts	177
Cabbage	140
Bibb lettuce	122
Asparagus	60
Okra	40
<b>Vegetable oils</b>	
Soybean oil	193
Canola oil	127
Cottonseed oil	60
Olive oil	55

Several novel orally effective small molecule factor Xa or thrombin enzyme inhibitor anticoagulants have recently been approved by regulatory agencies (rivaroxaban, dabigatran, apixaban, edoxaban, and betrixaban). The FDA has approved their usage in patients with CKD stages 1–4 (specifically CrCl  $\geq$  15 mL/minute as estimated with the Cockcroft–Gault formula). Moreover, apixaban and rivaroxaban have also FDA-approved dosing recommendations in hemodialysis patients. The EMA does not recommend the use of these drugs in dialysis patients [47]. High-fat, high-calorie diets tend to reduce the rate of absorption of dabigatran but overall drug availability is not substantially different from fasting [48]. Similar food interactions were shown for rivaroxaban [49]. Other important food interactions have not yet emerged. Since these drugs are in clinical use for only a relatively short period of time, other drug–nutrient interactions may come to attention.

Apixaban, edoxaban, and rivaroxaban are mainly metabolized through CYP3A4 [50]. Thus nutrients and food supplements that induce CYP3A4 such as St. John's wort might reduce drug levels and anticoagulant efficacy (Table 50.6). Overanticoagulation could occur with large amounts of citrus juice intake due to CYP3A4 inhibition (Table 50.5). Thus far, cases with either nutrient-dependent interaction have not been reported. For this reason, these drugs are not included in Tables 50.5 and 50.6. Betrixaban and dabigatran are not metabolized by CYP450 enzymes.

## Interactions of calcineurin inhibitors with nutrients

Treatments with cyclosporine A or tacrolimus continue to be part of immunosuppressive regimens that are used in kidney transplantation. Cyclosporine has several side effects that include nephrotoxicity, hepatotoxicity, hypertrichosis, gingival hyperplasia and hyperuricemia, and gout (7% of patients); the latter particularly when used together with loop diuretics. Cyclosporine is incompletely absorbed from the gastrointestinal tract, and the administration of the drug with foods tends to increase absorption. The incomplete absorption of intact cyclosporine is, in part, caused by metabolism in the small bowel wall [51]. Cyclosporine is metabolized by oxidation in liver microsomes through the CYP3A4 isoenzyme system. This enzyme system is also expressed in the small bowel wall which explains the first-pass metabolism of cyclosporine A. See also Tables 50.5 and 50.6.

Cyclosporine A is a highly lipid-soluble drug, and about 40% of cyclosporine in plasma is bound to lipoproteins. Thus it is reasonable to speculate that dietary fat intakes or the fat content of meals may raise the gastrointestinal absorption and plasma levels of cyclosporine A, but this has not been confirmed in clinical trials.

As indicated earlier, citrus juices, particularly grapefruit juice, reduce the metabolic rate of cyclosporine and raise its blood levels, possibly through the inhibitory effects of flavonoids and other compounds on CYP3A4 enzyme. The inhibition of CYP3A4 by grapefruit juice and other citrus juices and fruits raises the area-under-the-curve and causes an increase in 24 hours trough cyclosporine level (Table 50.5) [52]. St. John's wort and caspofungin induces CYP3A4 activity (Table 50.6). Both cyclosporine and tacrolimus can cause a number of metabolic complications, including phosphorous, magnesium or potassium depletion, hyperkalemia, glucose intolerance and diabetes mellitus, and hyperlipoproteinemia. Tacrolimus is mainly metabolized through CYP3A enzymes. Hence, food/food supplement interactions can affect tacrolimus blood levels: St. John's wort induces CYP3A and may decrease tacrolimus blood levels. Grapefruit juice that blocks this enzyme system increases blood levels (Tables 50.5 and 50.6). Drug inhibitors of CYP3A (calcium channel blockers, caspofungin, and azoles) can increase tacrolimus levels.

Absorption of tacrolimus from the gastrointestinal tract is substantially influenced by food: absorption is greatest with fasting. High-fat diets reduce tacrolimus absorption and drug availability more than high-carbohydrate diets [53].

## Nutrient interactions with potassium binders

Sodium polystyrene sulfonate (SPS), patiomer, and sodium zirconium cyclosilicate (ZS-9) are cation-exchange

compounds with either sodium (SPS, ZS-9) or calcium as counterion. SPS and patiomer are polymer resins, whereas ZS-9 is an inorganic silicate. As such, these compounds will bind other minerals than potassium in the gastrointestinal tract. Hypomagnesemia has been reported most commonly with patiomer compared to the other two binders [54]. The binding of nonpotassium cations can cause nutritional deficiencies and competitively reduces the efficacy of the binder to improve hyperkalemia. ZS-9 binds mainly protons in addition to potassium and increases the gastric pH which is thought to affect pH-dependent solubility of some other drugs.

The FDA-approved package insert for patiomer requires to take the drug with food. However, a recent clinical study demonstrated equal efficacy and tolerability if this potassium binder is taken with or without food [55].

### Nutrient interactions with phosphorus binders

Hyperphosphatemia worsens with progressing renal disease and is common and can be severe in hemodialysis patients. High serum phosphorus levels are causative in renal bone disease, as well as soft tissue, arteriolar (calciophylaxis), and vascular calcifications. High phosphate-containing foods include cheeses, dairy products, meats, and coca cola. As a rule, high protein intakes are associated with large dietary phosphate loads. Many processed foods contain phosphate compounds as stabilizers and preservatives.

Aluminum hydroxide is largely abandoned for chronic use as phosphate binder due to aluminum absorption and deposition in brain and bone causing dementia and bone disease. Magnesium-containing compounds are also not commonly used due to their risk of hypermagnesemia. Calcium-containing phosphate binders ( $\text{CaCO}_3$ , Ca-acetate) can increase calcium intakes above recommended amounts (800–1000 mg in CKD1–4 [28]) and appear to contribute to vascular calcifications [56,57]. Newer (calcium-free) phosphate binders include sevelamer (hydrochloride or carbonate), lanthanum carbonate, sucroferric oxyhydroxide, and ferric citrate.

In addition to phosphate, sevelamer also binds fat-soluble vitamins (vitamin D/calcitriol, E, K, and folic acid). This effect of sevelamer is not shared by lanthanum carbonate or sucroferric oxyhydroxide [58,59].

Iron-based phosphate binders, sucroferric oxyhydroxide, and ferric citrate were thought to have added benefits of supplying iron to patients with renal disease who often have iron deficiency. This did not materialize with sucroferric oxyhydroxide in clinical trials but ferric citrate improves transferrin saturation and hemoglobin in dialysis and predialysis patients [60]. With ferric citrate, there is a moderate risk of iron

overload in anuric dialysis patients, and monitoring of ferritin and transferrin is advised [60]. The citrate content of the latter drug can raise dietary aluminum absorption [60]. However, the aluminum serum levels increase only minimally and it is very doubtful that aluminum toxicity can arise solely from aluminum in foods.

Novel phosphate-lowering drugs that block the sodium-dependent phosphate cotransporter NpT2b or the sodium hydrogen exchanger-3 (NHE-3) in the intestine, namely, nicotinamide and tenapanor, respectively, are currently in clinical development [60–62]. Nicotinamide, a form of vitamin B<sub>3</sub>, is present in foods and food supplements. At pharmacological dosing (0.5–2 g/d), it reduces serum phosphate levels in hemodialysis patients similar to sevelamer [62]. Of concern is the systemic accumulation of the potentially toxic metabolite 2PY [62]. Tenapanor is a minimally absorbed small molecule direct inhibitor of the gastrointestinal NHE-3 [61,63]. It inhibits intestinal Na absorption, raises stool Na, and reduces urinary Na excretion [63]. The mechanism by which inhibition of NHE-3 reduces phosphate absorption is unclear but may involve indirect NpT2b inhibition. Tenapanor commonly causes diarrhea at high doses in a 4-week clinical trial [61], longer clinical studies are currently being performed. In normal subjects, stool phosphate excretion is greater if tenapanor is taken with food (before or after a meal) rather than in a fasting state [63]. Other drug–nutrient interactions with tenapanor are not known but clinical (trial) experience is minimal.

### Oral hepatitis C therapy and nutrient interactions

Hepatitis C is not uncommon in patients with CKD or those on chronic dialysis or in renal transplant patients. The introduction of direct-acting antiretroviral nucleotide and protease inhibitors has revolutionized the management and cure of patients with hepatitis C. These drugs are commonly used as single pill, fixed dose combinations of two or even three antiretrovirals, including novel combinations with pan-genotypic efficacy of  $\geq 96\%$  in the patients with normal renal function [64]. There is very little information about drug–nutrient interactions with these direct-acting hepatitis C antiretrovirals in general and in renal disease patients specifically. Almost all hepatitis C protease and nuclease inhibitors are CYP3A4 dependently metabolized and, hence, their antiviral efficacy is reduced by St. John's wort (Table 50.6) [20]; daclatasvir, simeprevir, and telaprevir are known to be affected by citrus (grapefruit) juice (Table 50.5).

## Nutritional implications of excipients in drugs

Excipients are therapeutically inactive additives in drug preparations that serve as solvents, solubilizers, or stabilizers. Most commonly, these compounds are inert. However, in some drug preparations excipients have substantial desirable or undesirable nutritional or metabolic effects [65].

Amprenavir (Agenerase, GlaxoSmithKline PLC, Brentford, Middlesex, United Kingdom), an HIV-protease inhibitor that is not marketed anymore in the United States, contained multiple excipients in its capsule or oral solution preparations, including vitamin E and propylene glycol. At therapeutic dosing the daily administered vitamin E amount was 1744 IU/d, or about 80-fold the recommended daily allowance and above the level considered toxic [66]. With the oral solution the propylene glycol intake (about 1.6 g/kg BW/d) could cause severe high anion-gap lactic acidosis in vulnerable patients (young children, pregnant women, hepatic insufficiency, renal failure, patients taking disulfiram, or metronidazole).

The ACE-inhibitor quinapril (Accupril, Pfizer, New York, NY) contains dose dependently up to 400 mg of magnesium which will be additive to the dietary intake of this mineral and may cause hypermagnesemia.

Polycarbophil (FiberLax, FiberCon, and other brand names) is an over-the-counter bulk-forming laxative that contains large amounts of  $\text{Ca}^{2+}$ . Each 625-mg tablet contains 140-mg  $\text{Ca}^{2+}$  and daily intakes at the recommended dose may exceed 1 g of calcium.

Propofol is poorly soluble in water and preparations contain 10% soybean oil to form an oil-in-water emulsion (causing the milky appearance of the intravenous preparation). Depending on dosing, the daily energy provision may exceed 1000–1500 kcal when propofol is administered as a continuous intravenous infusion in the intensive care units.

Other excipients include lactose (possibly symptomatic in patients with lactose intolerance), peanut oil (present in oral progesterone preparations and some valproic acid capsules; may cause severe allergic reactions in patients with peanut allergy), gluten (severe reactions in patients with celiac disease), and some chemical dyes such as tartrazine (FD&C Yellow No 5) which can cause severe complications especially in patients with aspirin hypersensitivity.

## Enteral tube feeding and oral drug administration

Enteral tube feeding may be a necessary or desirable mode of nutrient delivery in some patients with CKD or ESRD either transiently during periods of acute, severe

illness or for longer periods of time. In such patients, drugs may be administered preferably by intravenous routes, but enteral drug administration sometimes may be necessary, since many medicine preparations are not available for intravenous infusion.

Several considerations should be taken into account when giving oral drug preparations through enteral feeding tubes. First, oral medicines should be delivered into the stomach to ensure proper preparation for subsequent drug absorption in the jejunum. Second, drugs should be used in liquid form rather than as crushed tablets. Third, slow-release or enteric-coated tablets should not be crushed at all. Fourth, drugs may not be compatible with the tube feeding formula and should not be mixed with formula. Thus tubes should be flushed with water before and after drug administration. Fifth, the osmolality of some liquid drug preparations may be very high and may add to the osmolality of the formula. A complete list of commercially available liquid preparations of commonly used drugs has been published elsewhere [67,68].

Only few studies have examined the bioavailability of drugs when administered with enteral formulas, and this information is not available for most medicines. Effervescent potassium tablet preparations cause marked coagulation of the enteral formula, whereas potassium chloride or gluconate solutions are compatible [69]. Administration of aluminum-containing phosphate binders with some enteral formulas can lead to precipitation of formula proteins with the aluminum salts and gastrointestinal plug formation can occur. Case reports have suggested that enteral tube feeding causes resistance to warfarin. Apparently, this results from the antagonistic effect of vitamin K that is present in enteral formulas. In patients undergoing treatment with warfarin, a formula with a lesser vitamin K content should be used and will improve the response to the anticoagulant. There is also evidence that warfarin may directly bind to the feeding tube reducing drug availability [70]. Some drug compounds are light sensitive and inactivated by light exposure and preparation, and tube administration should be performed in the dark (nifedipine, nicardipine, metronidazole, amiodarone, and furosemide) [67].

Little is known about interactions of many other drugs that may be used in patients with renal failure undergoing tube feeding. Hence, close monitoring of the plasma drug levels, treatment response, and compatibility with the formula are necessary.

Prevention of frailty and improvement of  
physical performance

# Exercise training for individuals with advanced chronic kidney disease

*Thomas W. Storer*

Research Program in Men's Health, Aging, and Metabolism, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, United States

## Introduction

Individuals with advanced chronic kidney disease (CKD) exhibit malaise and significantly reduced capacity for virtually any form of exercise apart from self-care. These patients are commonly severely deconditioned, exhibit significant skeletal muscle weakness, and have abnormal muscle morphology, all of which lead to diminished physical performance, reduced quality of life, and increased mortality. For patients undergoing chronic dialysis, mortality is significantly related to the optimal dialysis dose [1], age, race, heart failure, physical functioning, and comorbidity scores [2]. In nondialyzed CKD patients, survival correlates with higher physical function and greater physical activity [3,4]. Of these predictive factors, only physical functioning and physical activity can be easily and directly improved. As illustrated in Fig. 51.1, sedentary behavior, which is especially prevalent in advanced CKD, is thought to directly effect a number of comorbidities, including inflammation, oxidative stress, and survival, although proof of a direct causal relationship between sedentary behavior and these disorders is lacking.

Exercise training has mitigated these negative effects in healthy individuals, and a growing body of evidence suggests similar outcomes in people with CKD. As with the general population, regular exercise training (planned, structured, repetitive, and purposeful in improving or maintaining physical fitness) [5] and increased physical activity (any bodily movement that results in energy expenditure) result in substantial benefits for persons with CKD.

Exercise programs for individuals with advanced CKD were introduced over 40 years ago [6]. Since then, a substantial body of evidence in support of exercise therapy in CKD has evolved through randomized controlled trials (RCT), systematic reviews, and meta-analyses [7–12]. Despite this evidence, renal rehabilitation programs have been neglected and lag far behind those for cardiac [13,14] and pulmonary [15,16] rehabilitation programs. Evidence-based guidelines for exercise training are also available for individuals with CKD [17,18]. These offer evidence-based guidance based on analyses of over 15 years of randomized, controlled trials of exercise training in people with CKD. The majority of exercise training outcomes and recommendations have been gathered from individuals with advanced kidney disease receiving dialysis, but the general approach to exercise training is applicable to individuals with CKD stages 1–5 [8,17,18]. There are no specific guidelines for exercise training in renal transplant patients.

This chapter provides nephrologists and the renal care team with a review of basic principles underlying exercise training, methods for assessing efficacy outcomes, and the variables used in exercise training program design. These are meant to provide the necessary background and guidance for exercise programming for patients with advanced CKD for whom exercise is beneficial. Additional resources for this purpose are provided at the end of this chapter. Finally, a renewed call to action is proposed for physicians and the renal care team to be more engaged with patients regarding exercise, emphasizing the value of regular physical activity and ensuring that exercise is part of the treatment plan.

### Impaired physical capability of advanced CKD patients

Individuals with advanced CKD commonly are severely deconditioned, inactive and have low tolerance for any physical activity beyond self-care [19–21]. The Dialysis Outcomes and Practice Patterns Study conducted in 12 countries with nearly 21,000 maintenance hemodialysis (MHD) patients reported that over half the sample acknowledged some type of exercise <1 day/week or never [22]. See Fig. 51.2.

Malaise, significant skeletal muscle weakness [23–26], and abnormal muscle morphology [27,28] are common characteristics of patients with advanced CKD. The cause of weakness is not entirely understood, but muscle atrophy, myopathy, deconditioning, malnutrition, and carnitine deficiency have been proposed as contributors [24,26]. Peak oxygen uptake ( $\dot{V}O_2$  peak), strength, and physical function levels in patients with end-stage renal disease (ESRD) are approximately 60%–70% of age-matched healthy individuals, even with the use of erythropoietin stimulating agents [25,27,29,30]. This low functional capacity contributes to low exercise tolerance, and poor physical functioning, anxiety, depression, and loss of sleep in patients with ESRD [31–33]. In a national study of over 2400 new dialysis patients, 75% described severe limitations in vigorous activities, and 42% of patients acknowledged severe limitations in moderate activities such as moving

a table or vacuuming [34]. Dialysis patients have significantly greater muscle atrophy in contractile areas compared with healthy controls, even when corrected for habitual activity level. The muscle atrophy is proportional to muscle weakness and reduced physical performance, as determined by gait speed [25]. In addition,

the limitation in peak oxygen uptake ( $\dot{V}O_2$  peak), the highest oxygen uptake achieved during an incremental exercise test and an indicator of functional capacity, may be due, in part, to impaired skeletal muscle function. However, this impaired skeletal muscle function may be improved with exercise training with consequent improvements in  $\dot{V}O_2$  peak.

Excitation–contraction coupling, central activation, and specific tension, when the latter is expressed as the ratio of maximal voluntary strength to contractile cross-sectional area (CSA), are not different between MHD patients and controls [24,27]. This suggests that muscle atrophy is a major cause of muscle weakness and the ensuing decrements in physical function. More than 60% of MHD patients are over age 65 and are sarcopenic [35]. Loss of edema-free lean mass in MHD patients, whether as a consequence of a chronic catabolic state, uremic myopathy, or decreased levels of androgens, growth hormone, and/or the insulin-like growth factor (IGF) system, is a common observation [36]. Comorbid conditions, including diabetes mellitus, obesity, heart failure, vasculitis, and other inflammatory diseases, may play an important contributory role. In addition to the myriad functional limitations experienced by those with CKD, the loss of edema-free lean body mass (LBM) common to this population may portend increased risk of mortality [37]. The Dialysis Morbidity and Mortality Study reports that mortality risks, expressed as relative risk (RR), were greatest in patients with ESRD who had severe limitations in moderate (RR, 1.72) or vigorous (RR, 1.51) physical activity when compared with those with minimal or no limitations. For MHD patients who exercised two to three or four to five times/week, mortality risks were substantially lower, RR = 0.74 and RR = 0.70, respectively [38]. It is eminently clear that individuals receiving MHD have an important need for interventions that mitigate the effects of ESRD on physical function and possibly morbidity, and mortality and that may reduce risks due to comorbidities, especially cardiovascular disease (CVD). Interventions that result in improved physical function would be welcome in the ESRD population. Well-applied and regularly practiced exercise training and increased physical activity is just such as intervention. Data collected for over 40 years in this area have demonstrated significant physical performance and health-related benefits in those MHD patients who reasonably comply with exercise training guidelines. Many of these benefits are presented next.

### **Demonstrated value of exercise and physical activity for people with CKD**

In the general population, lifestyle change, including physical activity and exercise training, are listed

among the highest priorities for improving health and reducing chronic disease risk. [39,40] Insufficient exercise and physical activity are well-known risk factors for many chronic diseases [41]. This is certainly true for the CKD population as the debilitating effects of CKD lead to the downward spiral of increased physical inactivity and increased comorbidity risk, especially that of CVD and increased mortality [42]. The National Kidney Foundation KDOQI Clinical Practice Guidelines recommend lifestyle issues, including physical activity, as a cornerstone therapy often with profound impact on patients receiving MHD [43]. Eight systematic reviews, some with metaanalyses, of exercise training effects in CKD have been reported in the last 9 years [4,7–12,44]; a summary of the effects of endurance (aerobic) training (AT), progressive resistance training (PRT), and combined aerobic and resistance training (CT) from these reports are presented in Table 51.1.

As indicated in Table 51.1, most data have been gathered from individuals undergoing MHD and provide an evidence base for the value of exercise training in advanced CKD. Clearly, more work is needed with nondialyzed CKD patients and renal transplant patients.

Over 40 years ago, Jette and colleagues reported a case study that investigated the feasibility of administering exercise training to a patient receiving MHD [45]. The twice-weekly exercise program conducted on nondialysis days was associated with improved functional capacity, improved mood, and decreased blood phosphorus levels. Patricia Painter, a research pioneer in the application of exercise training with MHD patients, investigated the effects of 6 months of thrice-weekly cycle exercise with the duration progressing up to 30 continuous minutes during the second or third hour of dialysis [31]. After 6 months a significant 23% improvement in  $\dot{V}O_2$  peak was reported with no change in the control group. Compliance in the training group was 91%. This study was the first to show that significant benefits could be achieved by regularly performing simple cycling exercise during the hemodialysis (HD) procedure. Now 33 years later, this seminal work has been confirmed many times, not only showing benefits for aerobic capacity but also for several other health- and performance-related variables (Table 51.1).

Aerobic capacity,  $\dot{V}O_2$  peak, that is, the maximum rate of oxygen consumption determined by progressively increasing work rate, is recognized as the best noninvasive parameter for assessing the integrated function of the cardiopulmonary and muscular systems [46–48]. Consequently,  $\dot{V}O_2$  peak has been studied extensively in MHD patients, and consistently increased  $\dot{V}O_2$  peak with exercise training has been

**TABLE 51.1** Summary of eight systematic reviews reporting outcomes from aerobic training (AT), progressive resistance training (PRT), and combined (AT + PRT) training in nondialyzed chronic kidney disease patients [nandrolone decanoate (ND)], maintenance hemodialysis (MHD) patients, and kidney transplant recipients (TR).

well documented [7,8,10–12,30,49,50]. The overall improvement in  $\dot{V}O_2$  peak in CKD patients (mostly those receiving MHD) who had undergone exercise training in these studies was about 23% or 4.3 mL/kg/min/min. This represents a 1.2-MET increase, where 1 MET is equivalent to the resting metabolic rate expressed as an oxygen uptake of 3.5 mL/kg/min. Although seemingly small, the 1.2-MET improvement in  $\dot{V}O_2$  peak may bring about important benefits. Evidence is now available that indicates that higher intensity exercise yields a better result and that combined aerobic exercise training and RT yields larger improvements in  $\dot{V}O_2$  peak than aerobic training alone [10].

Aerobic capacity is an independent predictor of mortality, has high prognostic ability, and outperforms traditional risk factors and other exercise test responses (including markers of ischemia) for predicting outcomes in people with and without CVD, patients with chronic heart failure (CHF), hypertension, diabetes, or obesity [51–60], even when estimated from treadmill time rather than from direct measurement [61]. Several studies have now shown in people without CKD that increasing aerobic capacity, especially in those with very low fitness, for example, a  $\dot{V}O_2$  peak <5–6 METs with maximal exercise (i.e.,  $\dot{V}O_2$  peak of 17.5–21 mL/kg/min) has a significant impact on reducing cardiovascular and all-cause mortality. In people without CKD, improving from this low fitness category, which is approximately the fitness level of MHD patients, every 1-MET increase in  $\dot{V}O_2$  peak reduces mortality risk by 10%–25% [62,63]. In 2011 Aspenes et al. studied the association between  $\dot{V}O_2$  peak and cardiovascular risk factors in 4631 apparently healthy Norwegian men and women [52]. In this cohort, every 5-mL/kg/min decrease in peak  $\dot{V}O_2$  was associated with a 56% higher odds of cardiovascular risk clustering. Inasmuch as many MHD patients often have some form of intercurrent CVD accounting for approximately 30% of their morbidity and mortality [64], improved their  $\dot{V}O_2$  peak should provide a significant benefit. In addition, increasing one's capacity for work decreases the relative percentage of that capacity that is required to perform at more common submaximal levels of functioning. Hence, exercise training regimens designed to improve aerobic capacity should be of significant benefit to patients with CKD and should be recommended and available to all.

Less is known about the prognostic ability of  $\dot{V}O_2$  peak in MHD patients. Sietsema studied 175 MHD patients who had completed cardiopulmonary exercise testing (CPXT) with measurement of  $\dot{V}O_2$  peak to determine its value in predicting survival [65]. There were 23 deaths during the 39-month follow-up period with 19 deaths in subjects who were below the median  $\dot{V}O_2$  peak of 17.5 kg/min and four deaths in the

subjects who were above the median, ( $P = .009$ ).  $\dot{V}O_2$  peak proved to be a better predictor of mortality than other traditional predictor variables. Although this was a retrospective study with a relatively small number of deaths, it supports the contention that increasing  $\dot{V}O_2$  peak through properly administered doses of regular exercise training in the MHD population might increase survival. Less is known about the association between improved  $\dot{V}O_2$  peak and mortality in nondialyzed CKD patients and chronic peritoneal dialysis (CPD) patients. However, trials conducted in nondialyzed advanced CKD patients suggest that appropriate exercise training can increase aerobic capacity and protect against the decline in cardiac function and progression of CVD through modification of risk factors [66]. More research that examines the causal nature of these relationships is needed, particularly in the predialysis CKD stages.

Loss of muscle mass, increased muscle weakness, and diminished physical performance are common in advanced CKD patients. Left unchecked, further muscle dysfunction and sarcopenia may ensue that lead to further weakness, loss of physical function, and progressively reduced quality of life and increased mortality. The most potent exercise countermeasure for these debilitating changes is PRT. PRT has not received the same attention as a training modality in CKD as aerobic training. However, in healthy individuals, adaptations to systematically applied PRT include increased LBM, skeletal muscle mass and fiber hypertrophy, improved muscle strength, power, and fatigability and improved physical performance. These changes have been reported for both men and women of all ages [67,68], including nonagenarian men [69]. Likewise, significant increases in muscle performance and LBM have been reported after PRT in patients with CVD [70], diabetes mellitus [71,72], Chronic obstructive pulmonary disease (COPD) [73,74], and those with HIV infection [75]. Based on these observations in healthy individuals and in patients with some chronic diseases, several studies have investigated the anabolic effects of PRT in CKD patients.

In the first study of resistance exercise training conducted during MHD, Johansen and colleagues compared changes in LBM and muscle size resulting from resistance exercise training, weekly injections of nandrolone decanoate (ND), or both interventions in a  $2 \times 2$  factorial design [76]. A total of 12 weeks of PRT alone did not prove to be an adequate stimulus for increasing LBM, but quadriceps muscle CSA increased significantly. Conversely, subjects randomized to receive ND experienced greater gains in these measures and the effects were additive in subjects receiving both ND and PRT (please see Chapter 52: Anabolic and anticatabolic agents in kidney disease and kidney failure).

Kopple and colleagues compared anabolic responsiveness in ESRD subjects randomized to 21 weeks of AT, PRT, combined AT plus PRT (CT), or nonexercising controls [77]. Importantly, total work done by subjects in the CT group was equal to both 50% of the endurance training (ET) group and 50% of the resistance training (RT) group. Changes in transcriptional levels of several growth factors in the right vastus lateralis muscle were used to examine the anabolic response to these modes of training. The subjects randomized to PRT alone exhibited no change in fat-free mass, determined by dual X-ray computerized tomography as well as no significant changes in several mRNA growth factors in the skeletal muscle other than increased levels of IGF-IEa mRNA. The mRNAs for IGF-IEa, IGF-IEc, and IGF-II each increased significantly in the CT group. There was a not-statistically significant trend in each of the three exercise training groups toward increased mRNA expression for most other growth factors. Myostatin mRNA decreased by 23% in the PRT group, but this change was not significant. The authors identified several factors that might have influenced these results, including the severe deconditioning and comorbidities of the patients in all groups, an inadequate training stimulus for the PRT group or the possibility of myopathies that might have impaired training responses. The lack of statistical significance in the foregoing changes might have been due to the small number of subjects in each group. When all three groups of the MHD patients who underwent exercise training were pooled, muscle transcriptional levels for other growth factors increased significantly, and the mRNA for myostatin decreased significantly.

An Australian group initially randomized 49 MHD patients to 12 weeks of intradialytic PRT or a no-exercise control to examine markers of muscle performance, physical function, body composition, and associated variables [78]. After interim measurements at 12 weeks, the trained subjects continued training for an additional 12 weeks, whereas the control group crossed over to the same PRT program as the original exercise group. The primary outcome variables were midthigh CSA and thigh muscle attenuation, an indicator of intramuscular lipid accumulation. After the first 12-week phase of the study, no significant improvement in thigh CSA was seen in either group. Thigh muscle attenuation decreased by 1.2% ( $P > .05$ ) in the PRT group reflecting a trend toward less muscle lipid content and therefore better muscle quality. This change was significantly different than the 0.34% increase in thigh muscle attenuation in the control group. At 24 weeks the change in thigh muscle CSA was significantly greater in the group that had trained for 24 weeks versus the crossover group who had

completed just 12 weeks of training. There was no difference in attenuation between the groups at 24 weeks. Substantial improvements in variables associated with an anabolic response such as strength and physical function were also observed.

Castaneda et al. examined the effects of a low-protein diet with or without PRT in a 12-week RCT of patients with chronic renal insufficiency. Despite the protein restriction, trained subjects had significantly greater improvement in several measures of muscle strength (average, 32% increase) compared to a 13% decrease in nonexercising subjects. In addition, the trained subjects exhibited maintenance of body weight and increased total body potassium and type I and II muscle fiber areas, whereas controls were observed to undergo a decrease in these measures; the differences in the changes were statistically significant [79].

In a 24-week study, Chen et al. demonstrated that MHD patients randomized to low intensity (sic) PRT (about 60% of their maximal voluntary strength) for the lower extremity conducted during the second hour of dialysis had significantly greater improvements in physical function (short physical performance battery, SPPB), knee extensor strength, and physical activity levels than subjects in the attention control group [80]. Similarly, some but not all studies of patients with CKD randomized to PRT, with or without added ET, showed significant improvements in muscle strength, 6-minute walk distance, stair climb performance, sit-to-stand transitions, self-reported physical function, and quality of life. Even an interdialytic modified yoga program resulted in significant improvements in handgrip strength relative to controls [81].

A recent systematic review and metaanalyses of seven RCTs assessed the effect of PRT on muscle strength (seven studies,  $N = 249$ ), skeletal muscle hypertrophy (six studies,  $N = 200$ ), and health-related quality of life (HRQoL) (six studies,  $N = 223$ ) patients with CKD stages 3–5 [9]. Studies were conducted over 8–24 weeks (average 14 weeks) with 3 days/week of training for six of the seven studies. Standardized mean differences (SMD) were used as an estimate of PRT effect relative to controls. Patients participating in PRT significantly improved standardized muscle strength (SMD = 1.15) and HRQoL (SMD = 0.83); the SMD for total muscle mass was 0.29 but was not significant. This is consistent with other studies of the PRT effect on LBM in CKD patients.

Limited and often inconsistent data do suggest significant anabolic effects in the form of increased muscle CSA, muscle fiber size, muscle growth factors, and their transcriptional levels, as well as decreased levels of myostatin and atrophic fibers from PRT interventions, particularly when combined with aerobic exercise training. Importantly, these changes are generally observed

with improvements in less proximal measures of anabolism (i.e., muscle function and physical performance) that are of important functional benefit.

Observational data suggest that regular physical activity may be beneficial for improving survival in MHD patients who typically are extraordinarily inactive [4,82]. One report showed 35% less activity than in sedentary healthy individuals [83] and two studies that analyzed physical activity data reported by over 2200 HD patients in the United States Renal Data System Dialysis Morbidity and Mortality Study Wave 2 reported a 62% greater mortality risk in patients who were sedentary (never or almost never exercised) versus nonsedentary (i.e., those with physical activity on <1 day/week to daily) at the time dialysis was initiated [38,84]. Although a causal relation is not yet proven or tested, the associative data so far available suggest that increasing  $\dot{V}O_2$  peak, muscle performance, physical function, and habitual physical activity in patients with CKD should be a high priority in their usual care, and specific exercise training and physical activity guidance should be considered part of routine therapy for the advanced CKD patient. Conspicuously lacking, however, are data on the sustainability of these positive changes, and whether there is sustained improvement in important health outcomes, such as survival, morbidity, and risk factors, especially cardiovascular risk factors [64]. Since most available data are based on studies of <6 month's duration, longer studies are needed to demonstrate whether sustainability of benefit does occur.

Results of studies examining the effect of exercise on urea clearance (Kt/Vurea) are mixed. Two studies found no change in Kt/Vurea after 8–16 weeks of moderate, 30- to 45-minute, cycle exercise during the HD procedure [85,86]. However, the effectiveness of exercise training on

urea clearance may not have been optimized in these studies, since exercise was conducted into the third hour of dialysis. In one 8-week study, 10–30 minutes of either aerobic or resistance exercise during HD had no effect on Kt/Vurea [87]. It is possible that the 10- to 30-minute aerobic or RT used in this study was of insufficient time or intensity to observe an effect on Kt/Vurea. Conversely, three studies reported 5%–19% improvements in Kt/Vurea [51,88,89]. A 2019 systematic review of the effect of intradialytic exercise on HD adequacy concluded that there was no overall exercise effect on Kt/Vurea although 6 of the 13 trials demonstrated medium-to-large effect sizes. Exercise did have an overall beneficial effect on phosphate removal. Interpretation of findings is difficult due to inconsistencies in the designs of the included studies, for example, RCTs (three), crossover (eight), or single group (two), and widely different exercise training regimens [90].

The possibility of improved dialysis efficacy shown in some studies might engender benefits for skeletal muscle and provide another advantage for intradialytic, as opposed to interdialytic exercise training [7]. However further research is needed wherein the exercise stimulus is optimized in RCTs.

### Principles of exercise training

There is an urgent need to establish expertly delivered, systematic, and regular exercise training in the CKD population. Members of the renal care team involved in recommending or delivering these programs should be aware of the basic principles of exercise that underpin effective exercise program design and progression. The principles of *Specificity*, *Overload*, *Progression*, *Individualization*, and *Reversibility* are summarized in Table 51.2.

TABLE 51.2 Summary of general principles of exercise training.

Specificity	The human body adapts or changes specifically to the type of training (physical stressor) imposed. For example, progressive resistance exercise training, PRT, is the preferred training modality to address loss of muscle mass and the ensuing muscle weakness [77,78] typical of individuals with advanced CKD. Unless one is very debilitated, aerobic exercise training is far less effective
Overload	“Overload” used in the context of exercise training defines a positive and necessary principle of “dose”: without increasing effort beyond the usual, little to no improvement will occur
Progression	For adaptations to improve, there must be overload as described previously. Progression is repeated overload until targets for risk reduction, physical function, or other clinically or patient-important outcomes are achieved
Individualization	Each person has unique physical capabilities and limitations due to age, medical history, exercise history, comorbidities, years on dialysis, etc. The exercise dose must be individually developed, applied, and monitored for responsiveness. They should be dynamic with the dose altered as the individual responds to the training stimulus
Reversibility	Failure to maintain a regular training schedule will result in loss of improvements. This occurs quickly in older adults and in people with chronic disease. Patients should be encouraged to remain as regular as possible with their exercise routines even if not with the recommended duration and intensity

CKD, Chronic kidney disease; PRT, progressive resistance training.

## The Frequency, Intensity, Time, and Type principle

Exercise training guidelines include specific variables for determining the exercise training dose. These are often referred to as the FITT principle: Frequency, Intensity, Time (duration of session), and Type of training. These variables may be manipulated for use in healthy individuals as well as in people with most chronic diseases, based on their ability. This is true for any type of exercise, including aerobic and resistance exercise training and flexibility, postural stability, and balance.

### Warm-up

The warm-up is designed to stimulate blood flow to the active muscles, increase body temperature, and enhance free, coordinated movement. Depending on the planned exercise intensity, a general 5- to 15-minute whole-body warm-up of gradually increasing intensity to the intensity target should precede the conditioning period. At rest, muscle receives only about 15%–20% of the cardiac output; during moderate exercise, this increases to about 70%. Beneficial effects of warm-up include increased muscle temperature through increased blood flow, increased myocardial blood flow, rightward shift of the oxyhemoglobin dissociation curve facilitating oxygen delivery, and possible reduction in cardiac dysrhythmias [80]. For resistance exercise, movement through the intended range of motion for the selected exercise with light resistance will provide a muscle-specific increase in blood flow and temperature and improved neuromuscular activation, greater conduction velocities, and faster activation of muscle fibers [81].

### Cooldown

In upright exercise a gradual decrease in exercise intensity over a 5- to 10-minute period prevents blood pooling in the lower extremities by maintaining the action of the peripheral muscle pump. Possible consequences of blood pooling include hypotension, fainting, and cardiac dysrhythmias [77]. Cooldown also facilitates heat dissipation and more rapid removal of lactic acid and catecholamines from the blood. Especially for dialyzed patients, a prolonged cooldown should be implemented to reduce the risk of hypotension following exercise and an emergency plan for episodic hypotension should be established and familiar to all of the health-care team working in the dialysis unit [90].

### Patient assessment

Assessing patients with CKD provides objective insights into their physical abilities, helps to quantify

exercise tolerance, aids in developing exercise training guidelines, and provides a baseline for monitoring progress and program efficacy [47]. These assessments may also be used to identify relationships between exercise intensity and symptoms such as cardiac abnormalities or musculoskeletal limitations.

Common assessments associated with exercise training and physical performance include measures of aerobic function (cardiorespiratory endurance), muscle performance, flexibility, and, in older individuals and in patients with chronic diseases, measures of physical function [4,91–94]. Table 51.3 summarizes several options for assessing health-related fitness and physical performance.

## Aerobic function and cardiopulmonary endurance

Assessment instruments for endurance performance include laboratory methods such as CPXT using incremental and constant work rate (CWR) protocols performed on treadmills or cycle ergometers [47,95]. Analysis of gas exchange data collected with metabolic measurement systems adds precision and allows evaluation of the integrated function of the cardiovascular, pulmonary, and muscular systems [47,48]. Key variables to measure during this assessment include peak oxygen uptake ( $\dot{V}O_2$  peak), the oxygen uptake ( $\dot{V}O_2$ ) at the anaerobic (lactate) threshold ( $\dot{V}O_{2\theta}$ ), as well work rate and heart rate at the time these markers of aerobic performance are obtained. Subjects' perception of effort using the subjective Borg 6–20 Rating of Perceived Exertion (RPE) scale [96], the Borg 0–10 category-ratio scale [97], the OMNI (omnibus) scale (a pictorial scale with ratings from 0 to 10 for cycling [98]), walking/jogging [99], and resistance exercise [100] or arbitrary 0–10 scales [39,101] aid the clinician in understanding the patient's perception of effort relative to objective physiologic indices. Additionally, these subjective data can be used later in designing exercise intensity prescriptions. Specific guidelines for administering and interpreting cardiopulmonary exercise tests assessments (CPXT, CWR, functional tests) have been published [14,48,102].

Because of the frequent occurrence of severe muscle weakness, most advanced CKD patients terminate an exercise test because of leg fatigue before a plateau in oxygen uptake is achieved, thus not meeting the primary criteria defining maximal oxygen uptake [46]. In addition to limitations in oxygen delivery (low hemoglobin, decreased cardiac output), there is often overall smaller muscle mass. In addition, advanced CKD/MHD patients, in comparison to healthy controls, often have dysfunctional mitochondria with impaired oxygen extraction due to significantly reduced cytochrome *c* oxidase activity, the catalyst for the final step in

<sup>a</sup>x-RM indicates the use of the number of repetitions used to assess strength. This could be one repetition (1-RM), three repetitions (3-RM), etc. For the fatigue test, 80% of 1-RM or 3-RM is this example would be used.

<sup>b</sup>NSRI-PF is North Staffordshire Royal Infirmary Physical Function Test. See Ref. [243].

mitochondrial oxidative phosphorylation [103]. Hence,  $\dot{V}O_2$  peak is considered the index of functional capacity in advanced CKD patients. Painter correctly points out, however, that  $\dot{V}O_2$  peak may not reflect the functional impact of exercise training in MHD patients [104]. Maximal incremental exercise testing investigates the limits of exercise tolerance, not the functional capabilities of work more commonly encountered in everyday life [105]. Submaximal CWR tests are particularly appealing in this regard, since these tests assess one's ability to sustain exercise at submaximal levels. In one study investigating the effects of 9 weeks of cycling exercise in MHD patients,  $\dot{V}O_2$  peak increased by 22% [32]. However, endurance time with a CWR test performed at 80% of baseline peak work rate increased by 144%, from 5.5 to 13.4 minutes. Improvements in  $\dot{V}O_2$  peak predict increased capacity for exercise and reduced health risks, but the large increase in CWR time suggests the potential for substantial improvements in the ability to perform everyday activities that may lead to improvements in quality of life.

When CPXT with gas exchange analysis is not feasible or is inappropriate, incremental and CWR cycle or treadmill tests can still be performed while monitoring blood pressure (BP), heart rate, electrocardiogram, and work rate. Time to peak exercise provides an index of functional capacity and peak work rate reflects exercise tolerance. Symptoms of exercise intolerance, including BP and ECG abnormalities, at submaximal work rates may be useful in setting exercise training intensities to avoid these signs and symptoms of intolerance.

Functional exercise tests such as 6-minute walk distance test [106,107] and shuttle walk test [108,109] are practical, time-saving, inexpensive and can provide helpful information for setting the exercise prescription

and for progress monitoring. Specific guidelines for administering the 6-minute walk test (6-MWT) and the shuttle walk test are available [106,109].

## Muscle performance

Muscle performance includes three specific functional attributes: strength, power, and fatigability (local muscle endurance). Maximal voluntary *muscle strength* is the greatest force that can be developed against a resistance. Testing for strength in healthy individuals is often attempted only once at a time to assess maximum strength; this technique is referred to as the one-repetition maximum (1-RM) procedure [110]. This method requires a gradual progression of increasing resistance to muscular movement to the maximum resistance that can be overcome for one repetition only. The 1-RM procedure has been administered safely in older people [32,69,111], and in people with various chronic disease states, including patients with COPD [112,113], cardiac patients [114–116], and CKD patients [7,78,117]. However, 1-RM tests may not be routinely appropriate for use in the ESRD population due to the higher risk for fracture and tendon rupture [118,119]. Spontaneous tendon ruptures have been reported in MHD patients [119] and tend to be associated with hyperparathyroidism and not with exercise. Nevertheless, caution is needed when assessing or training maximal muscle strength or power and should only be done by trained and experienced personnel. Alternatives to the 1-RM test include the 3-RM [76] or 5-RM [77,120,121] procedure in which resistance is gradually increased to the maximum level at which three or five repetitions can be performed in good form, and above which the resistance can no longer be overcome. The 3-RM and 5-RM have been shown to predict 1-RM with reasonable accuracy in healthy

individuals [122–124], but no studies have examined this prediction in CKD patients.

*Muscle power* defines the rate at which a muscle or muscle group performs work and can be expressed as force  $\times$  velocity. Power is associated with a variety of physical performance measures, including sit-to-stand transitions, stair climb time, and gait speed [32,125,126] and may be a better predictor of functional performance than strength [127–129]. Despite its strong association with physical performance, this metric of muscle performance has not been reported in resistance exercise training studies with CKD patients. This may be due in part to the technical difficulty of measuring muscle power without specialized equipment and the risk of muscle/tendon injury. A safe alternative that may be used as a surrogate for leg power measurements is the time taken to complete a number of sit-to-stand transitions (e.g., 5–10) [130].

*Muscle fatigability* is a measure of muscle endurance and the ability to sustain effort over time. Targeted exercises using a standardized resistance of 70%–90% of the 1-RM, 3-RM, or 5-RM can evaluate the ability of a particular group of muscles to make repetitive contractions at submaximal loads before fatigue leads to failure to complete the next repetition. Musculoskeletal limitations can be further evaluated and possibly treated through referral to a physical therapist or exercise physiologist. Assessment of muscle strength, muscle endurance, or muscle power may be used to develop the RT prescription, for monitoring progress, or to evaluate program efficacy. When used for these purposes, the type of resistance (Table 51.3) and movement pattern use for the assessment exercises should be identical to those used in training.

## Flexibility

Loss of flexibility contributes to restricted mobility in daily activities, particularly in older individuals. Since no single measurement indicates loss of flexibility at all joints [131], multiple or integrated tests of flexibility can be considered. The modified sit-and-reach test [132] primarily assesses hamstring flexibility and to a lesser extent, low back and calf flexibility in the sagittal plane; the standing trunk rotation test assesses the integrated flexibility of the ankles, knees, trunk, shoulder, and neck in the horizontal plane [133,134]. Test–retest reliability for these tests is high,  $r = 0.83$ ; interclass reliability is 0.98–0.99 in older adults [131,134,135].

## Physical function

Aging and chronic disease often bring about diminished physical function that contributes to increased risk of falls, fractures, disability, hospitalization, poor quality of life, and mortality [136–141]. Indeed, physical

function has been described as a mirror to an individual's health. [127,142–145]. Objective measures of physical function reflect the ease with which one performs typical activities of daily living, including walking, stair climbing, rising from a chair, and lifting and lowering objects. Many of these tests have been developed for frail older people [126] and as such often have ceiling effects when applied to other populations [146–148]. That is, when a person's ability reaches a certain level, they may have attained a maximum score with some tests; therefore no further improvement in the test scores is seen with increased ability. However, given the low functional ability of people with advanced CKD compared with healthy controls [149], many of the common tests of physical function may be entirely appropriate for this population. Several of these measures are summarized in Table 51.3.

Overend and colleagues studied the relative and absolute reliability of the 6-MWT and the number of sit-to-stand transitions completed in 30 seconds in a convenience sample of 25 men and women with ESRD [150]. Interclass correlations for the two functional measures were good (0.93 for both), suggesting good reliability, but the significant differences between trial 1 and trial 2 for the 6-minute walk (19-m) and chair stands (one repetition) suggest that it is important to use duplicate trials for these tests to ensure baseline stability. The minimal detectable changes determined from these data were 77 m for the 6-MWT and 2.6 repetitions for the chair stands.

The relative and absolute reliability of three physical function tests, the SPPB, the timed-up-and-go (TUG), and the one-legged stand test (OLST), were recently determined in 71 individuals receiving HD [91]. Participants were 21–90 years of age and performed duplicate trials for each test 2 weeks apart. Interclass correlations were  $\geq 0.90$ . Minimal detectable change scores at 90% confidence intervals for these tests were 1.7 points for the SPPB, 11.3 seconds for the OLST, and 2.9 seconds for TUG. It is important to note that the above noted minimal detectable changes are specific to the MHD population. Since the minimal detectable difference describes the random variability in scores of a truly stable participant, changes greater than these values can give confidence that a true change will have occurred within a stated confidence interval. Since the minimal detectable difference describes the random variability in scores of a truly stable participant, changes greater than these values can give confidence that a true change will have occurred 95% of the time.

Self-reported physical function has also been evaluated in MHD patients. Knight et al. reported hazard ratios for 1-year mortality in 15,000 MHD patients using the physical component summary (PCS) from

the SF-36 [151]. Compared to patients with a PCS score >50, individuals scoring 20–29 had a mortality hazard ratio of 1.62; those scoring 30–39 had a hazard ratio of 1.32, and patients whose PCS was <20 had a hazard ratio of 1.97. Patients whose PCS declined over 1 year had additional risk of mortality with an increased hazard ratio of 1.25 per 10-point decline in PCS score.

MacKinnon et al. systematically reviewed 29 studies in nondialyzed CKD patients exploring the association between survival rates and physical function (12 studies) or physical activity (17 studies) [4]. Self-report inventories reported in the review included the HRQoL [152] and Kidney Disease Quality of Life measure [153]. Overall, the authors reported a clear pattern of higher mortality rates or adverse clinical events with lower physical function and physical activity levels regardless of the instrument used for their assessment.

Objective measures of physical function are most desirable, but pragmatically, they require clinic time personnel and equipment. Alternatively, self-reports can be quickly administered in a clinic waiting room and provide a practical method of assessing the patient’s functional status that correlates with morbidity and mortality [4].

Application of exercise training program design for patients with CKD

The optimal dose of exercise training for advanced CKD patients is unclear [17,18,154]. Research shows large variability in responsiveness largely due to program design, execution, and individual differences [18]. However, analyses of recent studies and published recommendations from authorities on exercise for the CKD population [7,50,155,156] have helped disentangle

inconsistencies in exercise training recommendations for people with CKD. This has evolved into an evidence-based position statement on exercise in CKD [17] and an expert statement on exercise for people with CKD [18]. Guidelines for developing endurance (aerobic) exercise and progressive resistance exercise regimens for those with advanced CKD. These expert guidelines utilize the FITT principle and, like those for cardiac [70,95] and pulmonary rehabilitation programs [15,16], are patterned after existing, well-established guidelines for healthy younger [39] and older individuals [101] that have advanced since 1975 [157]. The 2008 [158] and 2018 [40] Physical Activity Guidelines for Americans from the US Department of Health and Human Services have contributed to the ease of understanding the guidelines and more widespread dissemination of the recommendations.

Objectives of exercise training for advanced CKD patients

Well-planned and systematic application of exercise training principles, setting clearly defined goals, and regular evaluation of physical functional ability are vital steps in establishing habitual exercise and increased physical activity. Strong encouragement from practitioners regarding these important behavior changes will help optimize improvement in fitness and physical function, risk reduction, and quality of life. Table 51.4 summarizes key steps for achieving these objectives.

When to exercise

Both intradialytic [31,32,51,52,76–78,80,85,104,159–165] and interdialytic [23,161,166–173] exercise training programs have been used successfully and safely in studies

TABLE 51.4 Objectives of exercise training for advanced chronic kidney disease (CKD) patients.

Assess individual patients for exercise history and physical functional abilities (see Table 51.3)
Develop safe and effective exercise training regimens and assist the patient in their successful implementation
Assist the patient in finding community resources for supervised exercise training. This could be a cardiac rehabilitation program
Provide guidelines for unsupervised exercise, for example, home exercise, as well as for lifestyle physical activity
Continually reinforce the importance of regular physical activity
Provide appropriate supervision and monitoring to detect changes in clinical status and provide ongoing surveillance data to the patients’ health-care providers to enhance medical management
Progressively increase exercise capacity, physical function, quality of life, and survival
Decrease risk factors associated with CKD and ESRD
Provide patient and family education to maximize secondary/tertiary prevention, for example, risk factor modification

ESRD, End-stage renal disease.

of MHD patients. In general, supervised programs are preferable, when possible. If training is conducted during an HD session, it should be done either before or during the first 90–120 min of treatment to avoid the risk of hypotensive responses. Unsupervised home programs have had mixed success.

Three studies have directly compared home versus supervised intra- or interdialytic exercise on various primary outcomes, including  $\dot{V}O_2$  peak,  $\dot{V}O_2$  at the anaerobic (lactate) threshold, 6-MWT distance, and aortic pulse wave velocity [161,162,174]. Patients randomized to supervised programs on nondialysis days had the greatest improvement from baseline in aerobic capacity, but they incurred the highest drop-out rates as compared with intradialytic training. Some improvement in the primary outcomes was demonstrated in all three of the exercise training schedules.

Parsons and King-VanVlack suggested that in addition to the attributes noted previously, exercise during dialysis may increase dialysis efficacy [64]. Movements of solutes from tissues to blood that then circulate through the hemodialyzer are rate-limiting

steps for the removal of many solutes, including uremic toxins. Exercise increases cardiac output and capillary blood flow, and thus exercise during HD may enhance the removal of dialyzable metabolites from tissues [29]. Thus intradialytic exercise may be the preferred exercise time, since it not only provides increased opportunity for supervision and adherence and makes use of what is otherwise a long bout of sedentary time, but it may increase dialysis efficiency. Moreover, by the end of the dialysis procedure, the individual is often fatigued and less willing to exercise later in the day.

### Guidelines: endurance exercise training for CKD patients

Current endurance exercise training guidelines for people with advanced CKD are summarized in Tables 51.5 and 51.6. For comparison, evidence-based guidelines for healthy younger and older individuals as well as for patients with CVD and COPD are included.

**TABLE 51.5** Summary of evidence-based guidelines for endurance exercise prescription in chronic kidney disease (CKD). Included for comparison are evidence-based guidelines for individuals with cardiovascular disease and healthy younger and older adults.

Group	Frequency (day/week)	Intensity	Time (min)	Type	Notes
Exercise & Sports Science Australia (ESSA) [17]	≥ 3	<i>Interdialysis</i>			
		55%–70% HRmax; RPE = 11–13 (6/20 scale) Prefer >60% HRmax	Build up to 30–45	Walking, cycling, other large muscle group exercise	Nondialysis days Build up to 180 min/week
		<i>Intradialysis</i>			
	3	55%–90% HRmax; RPE = 11–16 (6/20 scale) Prefer >60% HRmax	Build up to 30–45	Cycling	Exercise during the first 2 h of dialysis
	≥ 3	<i>Nondialyzed</i>			
		55%–70% HRmax; RPE = 11–13 (6/20 scale) Prefer 60%–90% HRmax	Build up to 30–45	Walking, jogging, cycling, other prolonged, rhythmic, large muscle group exercise	Adjust exercise dose according to patient needs
British Association of Sport and Exercise Sciences (BASES) [18]	≥ 3 Advise regular daily physical activity	“Moderate” ACSM criteria: 40–<60% $\dot{V}O_2$ reserve (see Table 51.4) RPE = 11–13/20	Individually determined	Cycling	Time examples: 15 min in intervals, for example, 3 × 5 min 20 min in intervals, for example, 2 × 10 min 20–30 continuous min

(Continued)

TABLE 51.5 (Continued)

Group	Frequency (day/week)	Intensity	Time (min)	Type	Notes
American College of Sports Medicine (ACSM) [95,252]	3–5	Moderate: 40%–59% $\dot{V}O_2$ R; RPE 12–13 on Borg 6–20 scale	20–60 continuous activity; if unable to perform exercise continuously, 3–5 min intervals with goal to accumulate 20–60 min	Prolonged, rhythmic activities using large muscle groups (walking, cycling, swimming)	Depending on clinical status and functional capacity, initial intensity should be light, for example, 30%–39% $\dot{V}O_2$ R; If intervals are used start with 1:1 work:rest ratio; initial training time can be set to 15 min and increased as tolerated to achieve 20–60 min
Special considerations during hemodialysis			Ideally, exercise nondialysis days; HR may be unreliable—use RPE to monitor intensity; Exercise during the first half of dialysis to avoid hypotensive episodes; avoid exercising arm with permanent A-V access		
Metaanalysis exercise in CKD [8]	3	“High intensity”	30–90 (includes RT)	Large muscle group, sustained exercise, for example, leg cycling, walking, jogging	These summary recommendations were stated as the strategy to “increase aerobic capacity as effectively as possible” and includes the recommendation of a 4- to 6-month supervised program
Cardiac rehabilitation (outpatient) [14,95]	Minimum = 3 Prefer $\geq 5$	If CPXT data are available: 40%–80% HRR or $\dot{V}O_2$ R or $\dot{V}O_2$ peak; Without CPXT <sup>a</sup> : HR rest + 20–30 bpm OR RPE = 12–16 (Borg 6–20 scale) RPE = 11–14; 40%–80% HRreserve or $\dot{V}O_2$ reserve Target heart rate < angina, ST-depression, BP thresholds; to tolerance	20–60	Large muscle group, sustained exercise, for example, walking, leg cycling, arm cycling, arm and leg cycling, rowing	Intermittent, short-duration exercise may be necessary initially; both continuous and interval training may be used
Healthy younger [32]	$\geq 5$ $\geq 3$ 3 + 2 $\geq 3$	Moderate <sup>b</sup> or Vigorous or Moderate + vigorous	30–60 20–60	Large muscle group, sustained exercise, for example, walking, jogging, leg cycling, arm cycling, arm and leg cycling, rowing, swimming	Target volume recommendations: $\geq 150$ min/week, higher amounts bring better results
Healthy older [72]	$\geq 5$ $\geq 3$	Moderate (5–6/10) <sup>c</sup> and Vigorous (7–8/10) <sup>c</sup>	$\geq 30$ $\geq 20$	Large muscle group, sustained exercise, for example, walking, jogging, leg cycling, arm cycling, arm and leg cycling, rowing, swimming	Duration should be accumulated in bouts of $\geq 10$ min Duration should be continuous for $\geq 20$ min/day

BP, Blood pressure; CPXT, cardiopulmonary exercise test; HR, heart rate; HRR, heart rate reserve defined as (HRmax–HRrest); RPE, rating of perceived exertion; Target Heart Rate, heart rate recommended during exercise training;  $\dot{V}O_2$ R, oxygen uptake ( $\dot{V}O_2$ ) reserve defined as ( $\dot{V}O_2$ max –  $\dot{V}O_2$ rest).

<sup>a</sup>CARDIAC: If maximal exercise test data are not available, THR = HRrest + 20 bpm with increases based on RPE, signs and symptoms, and normal physiologic responses.

<sup>b</sup>Healthy younger adults (18–65 years): Moderate intensity is 40%–59% HRR or  $\dot{V}O_2$ R; 64%–76% HRmax; 46%–63%  $\dot{V}O_2$ max; RPE = 12–13/20 (fairly light to somewhat hard). Vigorous intensity is 60%–89% HRR or  $\dot{V}O_2$ R; 77%–95% HRmax; 64%–90%  $\dot{V}O_2$ max; RPE = 14–17/20 (to somewhat hard – very hard). More favorable results are seen at higher intensities.

<sup>c</sup>Healthy older adults ( $\geq 65$  years): Moderate intensity is 5–6 on a 10-point scale. Vigorous intensity is 7–9 on a 10-point scale. Moderate and vigorous training may also be mixed when appropriate. More favorable results are seen at higher intensities.

TABLE 51.6 Methods for calculating relative endurance exercise training intensities and their equivalencies.

	% HR <sub>max</sub>	% $\dot{V}O_2$ max	% HR <sub>reserve</sub> or % $\dot{V}O_2$ reserve	RPE 6–20 [96]	RPE 0–10 [97]
Very light	<57	<37	<30	<9	0–1
Light	37–45	37–45	30–39	9–11	2–3
Moderate	64–76	46–63	40–59	12–13	3–4
Vigorous	77–95	64–90	60–89	14–17	5–7
Near maximal to maximal	≥ 96	≥ 91	≥ 90	≥ 18	8–10

%HR rate reserve is HR<sub>max</sub> – HR<sub>rest</sub>; %  $\dot{V}O_2$  reserve is  $\dot{V}O_2$  max –  $\dot{V}O_2$  rest; RPE 6–20 is Borg's rating of perceived exertion (RPE) Scale [96]; RPE 0–10 is Borg's Category-Ratio Scale of perceived effort and pain [97].

Adapted from Garber CE, Blissmer B, Deschenes MR, Franklin BA, Lamonte MJ, Lee I-M, et al. American College of Sports Medicine position stand. Quantity and quality of exercise for developing and maintaining cardiorespiratory, musculoskeletal, and neuromotor fitness in apparently healthy adults: guidance for prescribing exercise. *Med Sci Sports Exerc* 2011;43:1334–59. <https://doi.org/10.1249/MSS.0b013e318213fefb>.

## Frequency

Frequency defines the number of days/week for exercise and may vary with the medical and exercise history of the individual as well as with acute exacerbations. Training frequency may be different for different types of exercise, for example, aerobic and RT, although two or more types of exercise might be performed in a given session. For example, flexibility, endurance exercise, and resistance exercise could be performed during the same visit to the dialysis center.

Overall, patients with CKD should target endurance exercise of moderate duration on 5 or more days/week. Initially, 3 days/week might be an appropriate target to gradually adapt to unaccustomed exercise and to contribute to compliance. As fitness improves, achieving the evidence-based guideline of 5 days/week is recommended. For MHD patients, intradialytic exercise may be preferred where there is the availability of supervision in facilities that offer exercise training; this may improve compliance. When feasible, additional interdialytic exercise and physical activity should be recommended, ideally with supervision and guidance, but home exercise, such as walking or stationary cycling and/or modest resistance exercise training, should also be recommended. Logs of training sessions will assist practitioners in monitoring compliance and provide rationale for adjusting components of the patient's exercise training program.

## Intensity

Intensity refers to the level of exertion during exercise. Intensity can be prescribed and measured objectively or subjectively and may be expressed differently for different types of exercise. Examples of intensity metrics for different types of exercise are described next and summarized in Table 51.6.

Endurance exercise training for MHD patients should begin with lower intensities and progress to higher intensity as tolerated and safe. Evidence in healthy individuals suggests that intensity as low as 30%  $\dot{V}O_2$  peak or RPE of 10–11 would be an appropriate starting point for these patients [175–177]. Although some research studies have used percentage of HR<sub>max</sub> to guide training intensity in MHD subjects [86,104,162,163,169], it may be difficult to do so in these patients because of conditions such as underlying heart disease, especially with arrhythmias, autonomic dysregulation, changes in blood volume [178], medications such as  $\beta$ -blockers and some calcium channel blockers [95], and noncardiac-related limitations to exercise such as pulmonary disease [47] or myopathy [23,179,180]. The use of prediction equations from submaximal exercise variables, such as peak exercise time or treadmill speed and grade [181], or one of the commonly used HR<sub>max</sub> prediction equations such as  $208 - 0.7 \times \text{age (years)}$  [182] to predict HR<sub>max</sub> may be employed to select initial levels of exercise intensity [183,184]. A caveat to prediction of HR<sub>max</sub> is the attendant prediction error that may be >10 bpm [184]. Performing a clinical exercise test to peak exercise would improve the usefulness of heart rate indices for intensity prescription, since an actual HR<sub>peak</sub> would be obtained by this method. When the test is repeated with similar peak efforts, the reproducibility of HR<sub>peak</sub> is about  $\pm 2$  bpm. While this approach might be most useful in nondialyzed CKD patients, even objectively determined HR indices for training intensity for MHD patients may not be as reliable as other objective measures such as  $\dot{V}O_2$  or work rate (WR), if these data are available and are feasible to use. If objective data are not available to set the training intensity, use of one of the perceptual scales such as the Borg scales [96,97], the OMNI scales [98,99], or the 0- to 10-point scale advocated for healthy older individuals [101] could be used. Table 45.6 summarizes

several approaches to objectively and subjectively determine exercise intensity. Light-to-moderate levels of exertion would be the most appropriate choices for most MHD patients, at least until exercise becomes regular and fitness improves. At this point, higher intensity work might be introduced.

An example of a novel low-intensity exercise program administered at home was recently reported by an Italian group studying the efficacy of a 24-week low-intensity home walking program versus usual activity in 296 MHD patients [185]. Participants randomized to walking did so on 3 nondialysis days for 10 minutes twice each day in bouts of 5 minutes walking then 1-minute rest, repeated twice; the least fit group did five bouts with a 2:1 walk:rest ratio. Intensity was based on stepping cadence that was individualized using baseline 6-MWT distance. Cadence was set by a clip-on metronome given to each participant. Compared to controls, the walking group had significantly greater improvements in 6-minute walk distance, time to complete five sit-to-stand transitions, and scores on a kidney disease-specific QoL inventory. Dropouts from the walking group were more than twice as great as in the control group, 31% versus 14%. The entire program was managed by the dialysis staff who had been trained by the research team. Using step cadence as a measure of intensity was a clever, simple way to guide intensity.

High-intensity interval training (HIIT) is another option for more fit individuals with CKD. HIIT uses alternating bouts of higher and lower intensity exercise that has been used safely and effectively as a time efficient alternative to improve aerobic capacity in healthy people [186], in patients with COPD [187–189], heart disease [190–192], cardiometabolic diseases [193,194] and advanced CKD [195,196]. Examples of HIIT include high-intensity intervals of 80%–105%  $\dot{V}O_2$  peak alternated with lower intensity intervals (70%–70%  $\dot{V}O_2$  peak) in various ratios, for example, 1:1, 1:2, 4:3, 0.5:4 repeated four to six times. Burgomaster et al. trained eight healthy young men and women using four to seven 30-second maximal efforts on a cycle ergometer interspersed with 4-minute recovery periods [186]. A total of six training sessions were evenly distributed over 2 weeks. A control group did not train. Time to fatigue at work rates equivalent to 80% baseline  $\dot{V}O_2$  peak increased by 100% with no change in controls. This impressive improvement in endurance occurred after an average total high-intensity exercise time of 14–16 minutes and a total training time, including the rest intervals, of about 90 minutes over 2 weeks suggesting the time efficiency of this training method. Hwang et al. summarized findings of six RCT using HIIT compared with moderate-intensity continuous training (MICT) in cohorts of patients with cardiometabolic diseases [193]. Total energy expenditure between HIIT and MICT

groups was held equal. Adherence to HIIT was between 70 and  $\geq 90\%$ . Compared to continuous MICT, HIIT yielded significantly greater improvements in  $\dot{V}O_2$  peak; the weighted mean difference was 3.6 [95% confidence interval (CI), 2.28–4.91] mL/kg/min.

To date, only two randomized trials have tested HIIT in CKD patients [195,196]. In one study, 20 MHD patients were randomized to 22 weeks of twice-weekly supervised HIIT, MICT, or usual care [196]. Exercise was performed on a cycle ergometer at the dialysis chair and included an 18-minute warm-up. The HIIT group then completed three intervals of 3 minutes each at 85%–95% of HRpeak (15–17 on the Borg scale) interspersed with 4 minutes of active recovery at 60%–70% HRpeak. A 10-minute cool-down followed the last high-intensity interval. After warm-up, subjects in MICT completed an additional 27 minutes of continuous cycling at 50%–60% HRpeak that represented 11–13 on the Borg scale. Three, five, and three subjects in HIIT, MICT, and usual care groups completed the study. Dropouts included five individuals who received a kidney transplant. This pilot study reported no adverse events, but due to baseline heterogeneity in  $\dot{V}O_2$  peak, and the small sample size, it could not be concluded that the HIIT was superior to the MICT for improvement in  $\dot{V}O_2$  peak, 6-minute walk distance, or HRQoL. Interestingly, two of the three people completing HIIT improved  $\dot{V}O_2$  peak by 46% and 53% (group average +28%). Two of the five people in the MICT group improved by 18% and 36% (group average +4%). The median adherence for both exercise groups was 73%, and there was no difference between groups in enjoyment.

Another pilot study investigated the feasibility, safety, and efficacy of HIIT in stages 3 and 4 CKD patients by randomizing 14 such patients to 12 weeks of thrice-weekly treadmill exercise at HIIT or MICT [195]. The HIIT regimen consisted of four intervals of 4 minutes at 80%–95% HRpeak interspersed with 3-minute recovery intervals at 65% HRpeak. The MICT protocol required 40 continuous minutes of walking at 65% HRpeak. The study demonstrated that HIIT training was feasible and safe, but both groups exhibited similar changes in fitness measures, mitochondrial biogenesis or body composition. Subjects in both groups had similar adherence and reported the exercise as enjoyable. The authors stressed that safety was enhanced by thorough cardiac screening and a CPXT for all subjects prior to the study. Such screening may not be available in routine clinical practice suggesting great care when prescribing HIIT to CKD patients.

Although high-intensity exercise has been shown to be effective and safe in some patient groups, whether it is either appropriate, feasible, or effective for advanced CKD patients remains to be convincingly demonstrated. Since the prevalence of CVD in patients with advanced CKD is very high, it is strongly suggested that *every advanced CKD*

*patient* undergo coronary artery stress testing before they start any exercise program that substantially increases oxygen consumption. Ideally, the stress test would include imaging or ultrasonic evaluation of cardiac perfusion or function during exercise conditions. This evaluation will help reveal whether an individual can safely undergo exercise training as well as the training dose. As patients accommodate to regular exercise training, the careful introduction of interval training can provide variety and a greater stimulus for improvement. Much more systematic study with interval training in advanced CKD patients is needed before it can be universally recommended.

### Time (session duration)

Current evidence-based guidelines for endurance exercise time in healthy individuals [39,40,101] and non-CKD patient groups [13,16,95] suggest  $\geq 30$  minutes per session with a target of accumulating  $\geq 150$  minutes/week of endurance exercise training. An evidence-based position statement on exercise in CKD and an expert statement on exercise for people with CKD recommend building up to 30–45 minutes per session [17,18]. An individual's starting level of fitness and clinical status will help the clinician determine the appropriate starting session duration. An adage from the geriatric literature, "start low, go slow," is applicable here.

Thirty minutes of endurance exercise 5 days/week is a target milestone. Some CKD patients might be able to achieve this target from day 1. Individuals with more advanced CKD will likely need a shorter exercise time due to their significant deconditioning and low tolerance for exercise at least when starting ET. Examples include intervals in bouts of 5–10 minutes with total exercise time of 10–15 minutes. This can be progressed to longer bouts then continuously, as tolerated, to the target 30–40 minutes. Readers are referred to Ref. [18] for examples of initial short exercise session times that progress over 3 months for CKD patients.

### Type

Cycle ergometry performed at the dialysis chair is the most practical type of endurance exercise during an HD session. Most commercially available cycle ergometers require slight modification or adjustments in positioning to provide effective yet reasonably comfortable training. Ideally, patients undergoing exercise training during the HD session should be in a semirecumbent position while exercising so as to reduce the risk of hypotension or falling. For interdialytic exercise, available and patient-preferred types of aerobic exercise may be used. Whereas walking might be the most readily available and easiest type of exercise, other exercise modes such as cycling, swimming,

rowing, or arm cycling can be used. A metaanalysis of exercise training in MHD patients concluded that any mode of exercise training yielded a statistically significant difference in improvement in many health-related fitness and physical function measures when compared to nonexercising controls [7].

### Rest interval

During the initial phases of the ET program, patients may need periodic rest so that they can accommodate the exercise even though it may be at low intensity. No fixed time can be recommended; however, the practitioner should encourage the patient to resume the exercise as tolerated while maintaining the recommended training intensity. Also, recovery days in the early training phases should involve either no or only light exercise. With adaptation, more consecutive days of moderate-intensity activity can be added to the target.

### Progression

For CKD patients, increases in the duration of continuous exercise to target should be considered first. Afterward, increased frequency to target (ideally  $\geq 5$  days/week) is recommended followed by gradual increases in intensity. Dosing for exercise prescription is part science and part art. The well-trained practitioner should carefully monitor patient adaptations and provide guidance on when and how much to change exercise volume, the product of frequency  $\times$  duration  $\times$  intensity, which leads to calculation of MET-minutes or MET-hours per week. For example, 3 days of endurance exercise for 30 minutes/day (perhaps done continuously or in smaller bouts of time)  $\times$  moderate-intensity exercise of three METs (leg cycling at about 20 W) [197] equal 270 MET-minutes/week. The target is  $\geq 600$  MET-minutes/week, for example, 5 days/week  $\times$  30 min/day  $\times$  4 METs. MET values for conditioning exercises can be found in the 2011 Compendium of Physical Activity, available in eight languages. It may be accessed at <https://sites.google.com/site/compendiumofphysicalactivities/home> or in a simplified version in English at [https://download.lww.com/wolterskluwer\\_vitalstream\\_com/PermaLink/MSS/A/MSS\\_43\\_8\\_2011\\_06\\_13\\_AINSWORTH\\_202093\\_SDC1.pdf](https://download.lww.com/wolterskluwer_vitalstream_com/PermaLink/MSS/A/MSS_43_8_2011_06_13_AINSWORTH_202093_SDC1.pdf).

### Guidelines: progressive resistance exercise training in people with CKD

Resistance training guidelines for advanced CKD and chronic dialysis patients are listed in Table 51.7. For comparison, evidence-based guidelines for healthy younger and older individuals as well as for patients with CVD and COPD are included.

**TABLE 51.7** Summary of evidence-based and clinical practice guidelines for progressive resistance exercise training in advanced chronic kidney disease and maintenance hemodialysis patients, healthy young and older individuals, and cardiac patients.

Group	Frequency (days/week)	Intensity	Time (sets—reps)	Type	Exercises (number)	Notes
Exercise & Sports Science Australia (ESSA) [17]	<i>Interdialysis</i>					
	2 nonconsecutive days	12–15 RM or 60%–70% RM	1 set 12–15 reps	Weight-bearing activity; elastic bands or tubing; weight cuffs; dumbbells; weight machines	8–12 major muscle groups (MMG)	MMG: Quadriceps, Hamstrings, Calf Abdominals, Low back Pectorals, Latissimus dorsi Deltoids, biceps, triceps, Hip abductors and adductors
	<i>Intradialysis</i>					
	Before or during dialysis	12–15 RM or 60%–70% RM	1 set 12–15 reps	Weight-bearing activity; elastic bands or tubing; weight cuffs; dumbbells as practical	Up to 12 MMG	
British Association of Sport and Exercise Sciences (BASES) [18]	<i>Nondialyzed</i>					
	2 nonconsecutive days	12–15 RM or 60%–70% RM	1 set 10–15 reps	Weight-bearing activity; elastic bands or tubing; weight machines; free weights		
	2 nonconsecutive days	60%–70% 5-RM	2/3 sets 8–10 reps	“Resistance weights”	Dynamic leg exercise	Clinical status determines applications of the exercise guidelines
	2–3 nonconsecutive days	65%–75% 1-RM testing 1-RM not recommended Use $\geq 3$ RM to estimate 1-RM	Minimum 1 set 10–15 reps	Machines, free weights, bands	8–10 MMG	For most patients, target increasing sets as a goal
American College of Sports Medicine (ACSM) [95,252]	2–3 nonconsecutive days	60%–70% 1-RM (novice) 80% 1-RM (experienced)	1–4 sets 8–12	A variety of equipment and/or body weight can be used	MMG	< 50% 1-M to improve muscular endurance Rest intervals of 2–3 min between sets
ACSM Healthy younger (18–64 years) [39,95]	2–3 nonconsecutive days	60%–70% 1-RM (novice) 80% 1-RM (experienced)	1–4 sets 8–12	A variety of equipment and/or body weight can be used	MMG	< 50% 1-M to improve muscular endurance Rest intervals of 2–3 min between sets
Healthy older ( $\geq 65$ years) [95,101]	2–3 nonconsecutive days	40%–50% 1-RM (novice) 5–6 on 10 point scale	$\geq 1$ set 10–15 reps	A variety of equipment and/or body weight can be used	8–10 MMG	Nelson et al. [72] recommend moderate (5–6) intensity exercise with vigorous intensity (7–8/10) as an option for more fit and experienced people, preferably with supervision
Cardiac rehabilitation (outpatient) [115]		30%–40% 1-RM (upper body) 50%–60% 1-RM (lower body)	1–3 sets 10–15 without significant fatigue	A variety of equipment and/or body weight can be used	8–10 MMG	See Williams et al. [98] for details and contraindications; training loads might increase to 50%–80% 1-RM

### Frequency

Most existing guidelines suggest conducting PRT on 2 nonconsecutive days per week with the assumption that all major muscle groups are exercised on each of

the 2 days. Major muscle groups include quadriceps, hamstrings, triceps surae (gastrocnemius and soleus), abdominals, erector spinae (and other low back muscles), latissimus dorsi, pectoralis major, deltoids,

biceps, and triceps. If improvement in gait is a goal, exercise for the hip abductors and adductors and the gluteals should be added. When applied to patients exercising before or while undergoing MHD 3 days/week, it might be possible to enhance recovery with a more equal distribution of days, such as Monday and Friday or Tuesday and Saturday. People with CKD not receiving dialysis could improve the distribution of training days by performing PRT on Mondays and Thursdays or Tuesdays and Fridays.

An alternative to the 2-day/week regimen is splitting body parts that are exercised so that half are performed on 2 days while the other half is exercised on 2 other days. This may be more difficult when PRT is performed exclusively at the dialysis unit, but patients might be empowered to execute the fourth day at home. The current evidence-based exercise guidelines for people with CKD [17,18] recommend 2 nonconsecutive days/week for PRT.

### **Intensity (resistance)**

Intensity metrics used in RT include percentages of the one-repetition maximum (1-RM, the maximal load that was successfully moved only one time during an initial assessment), a prescribed number of repetitions before exercise failure, for example, 10–15 repetitions maximum, and ratings of perceived exertion. RT intensity guidelines are similar for advanced CKD and chronic dialysis patients with only the number of repetitions at a particular intensity being different [17]. Recommendations for MHD patients include one set of 12–15 repetitions or until fatigue using 60%–70% 1-RM on dialysis or nondialysis days. Individuals with advanced CKD not receiving dialysis are advised to perform 10–15 repetitions with at 60%–70% 1-RM or until fatigue [17]. Intensity recommendations for older individuals with severe muscle weakness and low threshold for exertional fatigue suggest two sets of eight repetitions using 60% of 5-RM (the maximum amount of weight that can be moved five times only) focusing on leg exercises [18].

The 1-RM test is highly effort dependent [94] and includes some risk of injury although the risk is minimized when properly administered by trained and experienced professionals. It has been safely administered to healthy individuals without musculoskeletal limitations [198], to pulmonary disease patients [79], lower risk cardiac patients [114,115], and to MHD patients [199,200]. Testing for 1-RM is very time-consuming and requires periodic retesting following strength gains. Another option uses a resistance that can be successfully lifted for a given range of repetitions, that is, 10–15 repetitions per set. These should be done in good form without reaching complete muscle failure. A total of 10–15 repetitions is roughly

equivalent to 65%–75% of 1-RM depending on the muscle group [110]. As training progresses, prescribed repetitions-maximum often decrease, for example, with increases in load, for example, 8–12 RM (70%–80% 1-RM). This method of repetitions to near failure is self-adjusting for progressing training loads as one becomes stronger. As a rule, when an individual is able to complete three consecutive training sessions with all prescribed repetitions, the load should be increased enough to maintain the prescription, for example, at 10–15-RM in good form to near failure.

An alternative approach makes use of subjective ratings of effort in which moderate exercise is equivalent to 5–6 on a 0–10 scale (0 = no movement) and high-intensity exercise at 7–8 on a 0–10 scale [101]. Borg scale RPEs have been used successfully in several trials of PRT in people with advanced CKD. Examples include moderate effort, RPE 11–15 [80,201] vigorous effort, RPE 15–17 [78] and RPE 6–10 in which 10 is “extremely hard” on a modified OMNI scale [100].

### **Duration (sets and repetitions)**

As with most guidelines for healthy older adults and patient groups, it is recommended that exercise training should begin with a single set of exercises for each major muscle group with 10–15 repetitions per set. Assuming that it will take one minute to correctly execute a set of 10–15 repetitions (4–6 seconds for a repetition) and 2 minutes for rest between sets, one exercise for each major muscle group can be completed in 25–30 minutes. With adaptation a second set can be added. See next for additional progression guidelines.

### **Type**

There are several forms of resistance that can be used for PRT. Simple elastic resistance (bands or tubes), weighted vests and ankle/wrist weights, dumbbell weights, kettleballs, and various machine weights are available. Newer resistance exercise equipment makes use of weighted bars and balls, weighted rubber tubes, and more. These forms of resistance can provide graduated resistance exercise starting at <1 pound.

Carrying out PRT in the dialysis chair may be advantageous. Cheema et al. described simple methods for conducting RT at the dialysis chair for all the major muscle groups [159]. Relatively inexpensive equipment, including dumbbells, ankle weights, and elastic bands/tubing, can be placed on a mobile cart and wheeled among patients. Bennett et al. have suggested that a specially built stack weight machine could be used at the dialysis chair for conducting lower extremity resistance exercise [202]. Another approach includes the use of weight machines before

starting the dialysis procedure [77], although limitations of space in the dialysis unit and the cost of this equipment may preclude this option. On the positive side, the visibility of exercise equipment may be motivating to the dialysis patients. These types of equipment can also be used for interdialytic PRT, but the approach described by Cheema et al. could also be easily and inexpensively adapted for home use.

### **Rest interval**

Rest intervals are often overlooked in guidelines for exercise training and are not infrequently left to the practitioner or individual to decide how to implement. For *resistance exercise*, rest intervals between sets are often guided by the training objective, health and fitness of the participant, and exercise training history. One minute rest between sets would be appropriate for people beginning PRT. Current evidence-based guidelines for healthy adults suggest 2–3 minutes for rest between sets in a regimen designed to improve strength. Shorter rest intervals may be used by more well-conditioned individuals particularly when the primary objective is muscle hypertrophy (45–60 seconds) or muscle endurance (15–30 seconds) [110]. Since most RT for all the major muscle groups is performed 2–3 days/week,  $\geq 1$  rest day should be given before exercising the same body part again.

### **Progression**

Progression of exercise is the sine qua non in RT and can be achieved in many ways by providing overload in the form of increasing sets, resistance, and number of training days per body part. After adaptation, increasing the number of sets from one to two may be the first choice for MHD patients. If time is available, a third day of PRT could be added. Since increases in muscle size and muscle strength are important outcomes in advanced CKD, increasing the load so that some or all of the training sets reach a high level of effort is desirable. For example, high levels of effort would be represented by 15–17, (hard to very hard) on the Borg 6–20 scale, or 5–7 (strong to very strong) on the Borg 0–10 scale. Finally, specific muscle groups might be targeted for additional emphasis. Since the muscles of ambulation are important for upright physical activity, including gait speed, and other lower extremity functions, additional PRT for quadriceps, hamstrings, hip abductors and adductors, and triceps surae could be considered.

### **Guidelines: enhancing flexibility**

Joint flexibility tends to decrease with age, but research shows that improvement in flexibility at any

age can occur after as little as three to four sessions of regular 2–3 days/week stretching [203,204]. Improving range of motion of joints through regular stretching is a useful adjunct to PRT for improving postural stability and balance [205,206]. Despite commonly held views, current evidence suggests that stretching is unlikely to be effective in reducing or preventing injuries, low back pain or delayed muscle soreness [206]. One RCT in MHD patients examined the possible benefits of a modified yoga-based exercise program [81]. After 24 15- to 30-minute yoga sessions distributed over 12 weeks, patients exhibited significant improvements in pain intensity, fatigue, sleep disturbance, grip strength, plasma levels of urea, alkaline phosphatase, total cholesterol, erythrocytes, and hematocrit, as compared to controls. Compliance was reported to be good.

### **Frequency**

Stretching is a low-intensity activity, thus conducting stretching activity  $>2$ –3 days/week is not likely to bring about negative consequences [207]. Daily stretching for those patients who could benefit from additional stretching sessions is acceptable and brings about greater gains. Stretching can be included, but should not solely comprise, the warm-up and/or cool-down phases of the training session. But providing dedicated time just for stretching is more likely to allow time to focus on this activity and to properly complete at least one good stretch for each of the major muscle–tendon groups.

### **Intensity**

The intensity of the stretch is determined by whether the final position achieved during the stretch is painful. It is recommended that the final stretching position should feel “tight” or slightly uncomfortable, but no actual pain should be experienced.

### **Duration**

As with healthy individuals, holding a static stretch either actively or passively for 10–60 seconds is recommended. A target of 60 seconds of total stretching time for each major muscle–tendon group should be eventually achieved.

### **Rest interval**

Rest between exercises or between stretching sessions is less of a concern because of the low intensity of stretching, assuming that the individual does not stretch to the point of pain. If one performs two or more 30-second repetitions of a stretch for the same muscle group, the next set can begin as soon as the individual feels ready.

## Progression

Progression in stretching includes increasing the duration of each stretch, adding additional stretching postures to individual muscle groups, and increasing frequency. Increasing intensity is not appropriate.

## Guidelines: improving balance and stability

Neuromuscular training that includes balance and postural stability exercises has been only recently included in guidelines for exercise and physical activity in healthy adults [207]. Exercise and other strategies to improve balance are particularly beneficial in older persons to reduce the risk of and fear of falling [205]. MHD patients have a higher rate of falling and greater morbidity from falls than the general population [208,209]. Risk factors for falls include fatigue and muscle weakness, both of which are exacerbated following an HD session [210]. Muscle weakness is a contributor to balance deficits, and in community-dwelling older people, exercise training is effective in reducing the rate of falls and risk of fall-related fractures [211]. Although there are no specific guidelines for implementing balance/stability exercise, it is reasonable to consider balance exercises such as semitandem and tandem stands, one-legged stands, and especially more dynamic balance, coordination, and agility activities such as Tai Chi. Tai Chi has been extensively investigated, with several studies reporting its effects on improving balance, reducing falls [212,213], and improving motor control.

Kaesler et al. reported a novel, uncontrolled postural stability program that uses "Pilates-inspired" exercises [214]. Eight community-dwelling adults, aged 66–71 years, were assessed for static and dynamic postural sway using a validated sway meter. Physical function was measured with a four-part balance test, a TUG, and a single sit-to-stand test for time followed by a sit-to-stand test where the number of transitions was timed over 30 seconds. Subjects then completed 8 weeks of twice-weekly 40-minute conditioning sessions. Each session consisted of performing 12 exercises with 15 repetitions of each exercise. Details of the exercises are available [214]. Significant improvements were seen in postural sway and the TUG. This work is encouraging, but the small sample size and lack of controls suggest the need for a more scientifically rigorous study of this method.

## Risks of exercise in the advanced CKD patient

There is a lack of specific reporting of adverse events associated with exercise training in advanced

CKD patients [7]. However, for MHD patients, both intra- and interdialytic exercise training are generally thought to be safe as reported in systematic reviews [7,17,18,50]. In healthy exercising individuals the most common injuries experienced are musculoskeletal [215], and the most consistent association is between intensity and/or greater total volume of exercise over time and higher risks of injury. This is not surprising, since the total amount of exercise (volume) is the product of the intensity, duration, and frequency of exercise. For healthy and patient populations alike, injuries can be effectively mitigated by appropriate screening, warm-up, and progression in the components of the exercise prescription. In most MHD patients the risk–benefit ratio generally favors exercise [17,50]. Instruction in proper technique, breathing, adherence to the recommended program, and reporting untoward responses to members of the health-care team are important preventative strategies.

As with healthy individuals, musculoskeletal injuries are the most common risk in exercising CKD patients, but other risks, particularly of cardiac origin, are more serious and are most often seen with high-intensity exercise [7,216]. Patients with CKD often have underlying cardiac disease, thus increasing their vulnerability to exercise-induced adverse cardiovascular events. However, no negative hemodynamic effects have been reported with exercise during MHD, and in fact, systolic BP (SBP) stabilizes during such exercise [29]. The greatest exposure to exercise-induced cardiopulmonary stress occurs at peak exercise; but to date, there are no published reports of adverse cardiovascular events associated with exercise testing or training in MHD patients [156]. Nonetheless, it is not uncommon for MHD patients who have no history of coronary artery disease or ischemic heart disease and who volunteer for exercise training to be found to have electrocardiographic evidence of ischemic heart disease on stress testing. Thus advanced CKD patients must be evaluated carefully for ischemic heart disease both before they are allowed into an exercise training program and they participate in such a program.

About 45% of MHD patients are diabetic [217]. Consequently, serum glucose control during exercise may be of concern. Exercise during dialysis may prevent hypoglycemia since the dialysate glucose will serve as a form of a glycemic clamp, with serum glucose levels drifting toward the dialysate glucose concentration, which is usually about 100- to 200-mg glucose monohydrate/dL [156]. Nevertheless, monitoring of serum glucose levels is appropriate if the MHD patient is diabetic and is taking hypoglycemic medications. These individuals should learn to balance quality and quantity of food intake, insulin, and exercise intensity and duration.

Advanced CKD is often associated with decreased bone mass and changes in bone architecture. [218]. These changes may worsen as CKD progresses. Consequently, fracture risk is higher than in healthy individuals. Jamal et al. reported that increased fracture risk was associated with impaired muscle performance [118]. It is likely that the appropriate inauguration, progression, and type of exercise training will help to avoid fracture risk and perhaps reduce it [11]. Huang et al. have suggested that increased exercise time is positively associated with femoral neck and lumbar spine bone mineral density, and that exercise training is positively correlated with these measures, although these relationships did not reach statistical significance [11]. Spontaneous tendon ruptures have been reported in MHD patients [119] and tend to be associated with hyperparathyroidism and not with exercise. Only one trial has specifically studied exercise-induced injuries or adverse events [78] with no statistically significant differences between the resistance-trained group and inactive controls over the 12-week study. One older female MHD patient experienced a partial tear of the supraspinatus muscle in week 6 of exercise training, but she continued to train with lower extremity exercises [219]. Studies specifically examining the injury versus exercise dose–response relationship for various modes of exercise training in MHD patients are needed. As recommended in Heiwe’s systematic review, future RCT should specifically examine the frequency and nature of injuries and adverse events with special consideration for the dose and type of exercise [7].

## Barriers to overcome

MHD patients encounter significant impediments to maintaining a regular exercise program both within and outside the dialysis center [50,220–222]. Commonly reported barriers to participation include fatigue, transportation limitations [222,223], lack of encouragement [223], and low motivation [224]. The recently reported Network 11 study of physical activity in 1323 ESRD patients revealed that lack of motivation, fatigue, perception of being too sick, and no place to exercise or lack of exercise equipment were the most frequently cited barriers to participation in physical activity [225]. Lack of motivation, the most frequently reported perceived barrier to participation in exercise [224,226], has also been associated with less physical activity [221]. Barriers to conducting exercise training in the dialysis center have been reported [227]. Dialysis center staff may not encourage or facilitate the ability of patients to exercise before, during or after an HD session, because the staff is very busy with many demands on its time or there is concern about the risks of exercise or

uncertainty regarding its benefits [24]. Dialysis staff also may be reluctant to encourage exercise among dialysis patients, because they believe it is not their responsibility to do so, and they usually do not have the skills to implement exercise training [224]. Probably of particular importance is that the dialysis staff and health-care worker to patient ratios in chronic dialysis units in the United States generally allow little time for dialysis staff to spend time on encouraging, assisting, and monitoring exercise training of patients.

Two studies have revealed that nephrologists typically do not counsel their patients regarding exercise, query physical activity or exercise habits, or provide guidelines for implementing exercise training [221,228,229]. Interestingly, while the vast majority of nephrologists agreed that exercise was potentially beneficial, the physicians surveyed thought that dialysis patients would not be interested in learning about exercise, were concerned about the risks of exercise, and believed their patients would not increase their physical activity even if counseled to do so [228]. Counter to these physician opinions, a separate study of patients receiving MHD indicated that they would increase physical activity if recommended by their physician [221]. A 2019 focus group study confirmed these findings by reporting that the lack of advice from kidney care providers regarding exercise was a significant barrier to participation, and that exercise interventions should include counseling and prescribing exercise by nephrologists [229].

These problems are compounded by lack of interest and lack of training on the part of nephrologists and dialysis center staff as well as lack of appropriate exercise equipment and space. The latter impediments have been overcome using simple, inexpensive cycle ergometers [31], and resistance exercise equipment [230]. Novel weight machines have also been developed for RT while the patient is situated in the dialysis chair [202].

## Safety and contraindications for exercise

Smart et al. reported that exercise training conducted during the course of research on MHD patients is safe. No deaths were reported in over 28,000 patient-hours of exercise in the studies included in their systematic review [30]. However, since patients with advanced CKD have a greater prevalence of heart disease than is present in the general population [231], a CPXT with 12-lead ECG and BP monitoring would be indicated in all adult patients with advanced CKD, MHD, CPD, and kidney transplant patients prior to beginning exercise training. Relative and absolute contraindications for exercise are available from the American Heart Association [70] and the American College of Sports Medicine [95].

Hypertension is common in CKD with a prevalence approaching 70%–90% in MHD patients [11]. The American College of Sports Medicine suggests that a resting BP > 180/110 is a contraindication for exercise. Clinical judgment may, however, modify this guideline based on patient history, health status, BP responses to a particular dose of exercise, and the benefit-to-risk ratio. A recent metaanalysis reported nonsignificant differences in changes in both SBP and diastolic BP (DBP) after varying amounts of exercise training [11]. SMD (95% CI) were  $-0.17$  ( $-0.41, 0.08$ ) for SBP and  $-0.23$  ( $-0.69, 0.24$ ) for DBP. Patients with CKD should be educated about abnormal responses, symptoms, when to not exercise or to stop exercise and to report these findings to their health-care professional [252]. BP should be monitored often to ensure safety during exercise training. A particular concern for increased BP during exercise is evident during resistance exercise training if a participant holds their breath while straining to move a resistance, that is, the Valsalva maneuver. This is a safety risk that can be virtually eliminated by teaching proper breathing techniques during resistance exercise training. The simplest instruction is simply “keep breathing; don’t hold your breath while exercising.” Some exercise trainers suggest regulating the breathing so that the participant exhales normally while making the effort against a resistance and inhaling when the resistance is moved back to the starting position. Either approach will avoid a Valsalva maneuver.

As noted previously, fragility fractures and spontaneous tendon ruptures have been reported in advanced CKD and ESRD patients, primarily due to hyperparathyroidism. Care in selecting the resistance during PRT or strength testing will help to avoid these problems.

Exercise during dialysis can result in fluid and electrolyte shifts that may contribute to exercise intolerance and the possibility of hypotension associated with the dialysis procedure [155]. Careful observation of the participant is important and may result in recommending that the patient decrease the work rate or stop exercising entirely on that day. Exercising only during the first 90–120 minutes of the HD session will often avoid these problems [17,95].

### **Urgent need for development of renal rehabilitation programs**

Over 35 years of research on exercise training coupled with the systematic reviews and metaanalyses of these studies provide compelling evidence of the substantial benefits to CKD patients who participate in regular exercise. Prescribed exercise doses have been

expertly developed and are systematic and comprehensive (Table 51.1). Although these encouraging data suggest here is improved HRQoL and greater survival with exercise [232], it is an uncommon feature in the lifestyles of most MHD patients. Indeed, two recent surveys of chronic dialysis patients reported that only 13% [225] and 17% [222] of respondents achieved the commonly recommended guideline of 150 minutes/week of moderate-intensity exercise. One international study of 21,000 MHD patients reported that over half of those surveyed exercised 1 day or less/week (Fig. 51.2) [233]. The downward spiral of decreasing physical ability consequent to ESRD, and possibly to the chronic dialysis treatment itself, may lead to marked increases in a sedentary lifestyle that leads to further decrements in physical ability and performance. Unless broken, the spiral continues downward toward disability. Clearly, we must do more to remove barriers to exercise and encourage greater participation to target levels of exercise and beyond. There have been several calls to action [49,155,228,232,234–236] to increase the participation of MHD patients in regular exercise and the time for formal “renal rehabilitation” is never more present than now. Encouragingly, currently, there are enthusiastic people who are forming an Exercise in CKD Working Group in the United States [237]. Similar groups are established in Canada, Europe, and Australia. A major reorientation is needed in how to engage advanced CKD patients in physical activity and sustain that engagement. Evidence suggests that the nephrologist and related health-care staff are the individuals who are best positioned to effect this change.

### **Implications for practice**

The 2005 Clinical Practice Guidelines for Cardiovascular Disease in Dialysis Patients [138], suggested that “All dialysis patients should be counseled and regularly encouraged by nephrology and dialysis staff to increase their level of physical activity.” (guideline 14.2); “The goal for activity should be for cardiovascular exercise at a moderate intensity for 30 minutes on most, if not all, days per week. Patients who are not currently physically active should start at very low levels and durations, and gradually progress to this recommended level.” (Guideline 14.2.4.a.i)

“Physical functioning assessment and encouragement for participation in physical activity should be part of the routine patient care plan. Regular review should include assessment of changes in activity and physical functioning.” (Guideline 14.4.b.i)

These guidelines provide simple, valuable steps that all renal care practitioners can implement. Evidence-based guidelines for exercise training in CKD are

available to the practitioner for endurance (Tables 51.5 and 51.6) and resistance exercise training (Table 51.7). These guidelines provide a basic framework for increasing participation in exercise and increased physical activity, but more detailed and comprehensive guidance is lacking. Given the low exercise tolerance of most advanced CKD patients, almost any increase in physical activity will be beneficial and should lead to progression in frequency, duration, and intensity of training and to enhanced benefits. The findings that low training loads and volumes have been shown to be capable of stimulating improvement [185] suggest a large adaptation window because of the significant debility of ESRD patients. The use of the AIDES method [238] shown in Table 51.8 may facilitate participant adherence to the exercise intervention.

Of clear importance is the need to remove barriers to participation in exercise training and physical activity as noted previously. There is a need to increase the nephrologist’s knowledge base and willingness to educate his/her patients that regular exercise training may improve their walking capacity, physical fitness, and possibly overall health. Physicians should determine the activity level of patients and encourage them to reach the targets for the type, frequency, duration, and intensity of exercise outlined in this chapter. Real and perceived barriers to participation in regular exercise and physical activity should be investigated and addressed. Since maintaining an in-center exercise program falls largely on the clinical staff, their training and support are vital [222–224,229]. Engagement in regular exercise for the MHD patient might be better facilitated at the chronic dialysis center that has the potential advantages of equipment availability, supervision, and monitoring. However, regular exercise training can also be successful in outpatient supervised settings or in community-based programs [216]. Home exercise, including simple walking, is also useful in augmenting daily physical activity and for achieving the 150 minutes or greater per week physical activity target.

These are difficult tasks for many physicians who may not have the time, training, or desire to advise and monitor effective exercise training for their

patients [222]. However, Painter [234] has suggested that even within the constraints of short patient visits, physicians can do the following:

- Ask the patient about physical activity, and help identify barriers to exercise and physical activity.
- Recommend increasing physical activity, if levels are low, by recommending walking when feasible and appropriate.
- Provide such educational materials as
  - “Exercise for the Dialysis Patient” available free from [LifeOptions.org](http://LifeOptions.org), a rehabilitation program dedicated to those with kidney disease.
  - “Getting Motivated to Exercise” available online from the National Kidney Foundation (United States) at [https://www.kidney.org/news/monthly/Getting\\_Motivated\\_to\\_Exercise?homeslider=Option](https://www.kidney.org/news/monthly/Getting_Motivated_to_Exercise?homeslider=Option).
  - “Strategies for Improving the Effectiveness of Exercise in Dialysis Patients” American Kidney Fund by Kenneth Wilund, PhD. Available online as a slide presentation at <https://www.kidneyfund.org/assets/pdf/training/exercise-training.pdf> This presentation is also available as a YouTube video narrated by Dr. Wilund. <https://www.youtube.com/watch?v=DFbOLhURpqY>.
- Refer to a trained health-care professional who is qualified to work with exercise for patients with chronic disease, such as physical/occupational therapists, cardiac rehabilitation specialists, or clinical exercise physiologists.
- Referrals can then be regularly followed up during the routine clinic visits to assess participation and progress and to provide encouragement.

For the interested physician or health-care provider, help is available in the form of a national initiative sponsored by the American College of Sports Medicine called Exercise is Medicine. Shared with the American Medical Association, the guiding principles of Exercise is Medicine are designed to help improve the health and well-being of the nation through a regular physical activity prescription from doctors and other health-care providers. Many resources for physicians and

TABLE 51.8 Adaptation of the AIDES method [238] for improving adherence to exercise training and physical activity.

A:	Assessment (see Table 51.3)	Assess all components of health-related fitness and physical performance
I:	Individualization	Individualize the exercise training regimen
D:	Documentation	Provide written guidelines and progress monitoring
E:	Education	Provide accurate and continuing education tailored to the needs of the individual
S:	Supervision	Provide continuing supervision of the regimen

health-care workers are available through Exercise is Medicine and include Exercise is Medicine Health Care Providers' Action Guide, Exercise is Medicine Action and Promotion Guide, Billing and Coding for Physical Activity Counseling, ACSM's Exercise is Medicine: A Clinician's Guide to Exercise, and National Center on Physical Activity and Disability brochure for Health Care Providers. Detailed information is available at <https://exerciseismedicine.org/physicians.htm>.

Assistance is also available from American College of Sports Medicine Clinical Exercise Physiologists. These allied health professionals are trained and certified to assess, design, and implement exercise/fitness programs and provide education and counseling for individuals with chronic health conditions (e.g., heart disease, diabetes, cancer, lung disease, and renal disease). As such, they would be valuable members of the renal rehabilitation team.

### Summary

This chapter has sought to provide physicians and other related health-care providers with a summary of current evidence for the value of comprehensive exercise training and increased physical activity for the patient with CKD. Basic principles underlying exercise training are reviewed, and specific methods for assessing health-related fitness and physical function in CKD patients are presented. The common elements that guide exercise training program design for endurance and resistance exercise, flexibility, and stability are presented along with specific applications for CKD patients. Sufficient detail is provided to guide clinical practitioners toward implementing exercise training programs for their patients. Some of the predominant barriers to participation are identified along with risks and safety for exercise training in CKD.

More data on exercise training efficacy in people with CKD stage 2–4, CPD patients, and renal transplant recipients are needed with careful research design and adherence to guidelines that guide high-quality studies. There are presently little to no data on the long-term effectiveness of exercise training in people with any stage of CKD. Properly administered exercise training has been shown to be of great short-term benefit, but we do not know whether the improvements are sustainable.

Finally, a renewed call to action is expressed in conjunction with the implications for implementation of exercise training programs for patients with CKD. There is an urgent need for physicians and associated staff who work with CKD patients to regularly inform them of the value of physical activity, assess current

physical activity and physical function status, and moderate barriers to participation. These health-care workers should encourage regular exercise and increased physical activity and ensure that the appropriate intensity, duration, and frequency of exercise are added to the treatment plan. Resources for physicians and health-care practitioners for increasing knowledge and skills in exercise prescription and training for patients are provided. We can expect to see advances in evidence-based exercise training guidelines for CKD patients as research continues to elucidate specific applications of the FITT principle.

There are clear-cut benefits for improved performance and physical function awaiting patients who regularly exercise. A sea change is needed in the manner in which patients with CKD engage in physical activity, and evidence suggests that the nephrologist and his/her associated staff are the individuals who are best positioned to effect this change. The time for formal "renal rehabilitation" is never more present.

## Introduction

Chronic kidney disease (CKD), and particularly end-stage renal disease (ESRD), is associated with muscle wasting that contributes to muscle weakness, poor physical function, and increased mortality [1]. Many factors related to CKD and ESRD, such as inflammation, poor nutrition, chronic uremia, and androgen deficiency converge on pathways regulating muscle mass to drive catabolism, inhibit anabolism, or both. Thus multiple therapeutic targets in these pathways have been studied in the hope of preventing, decreasing, or mitigating muscle wasting and even increasing muscle strength and physical function in those with CKD and ESRD. This chapter will review and discuss many of these therapeutic targets that have been investigated in clinical trials recently and over the preceding decade (Fig. 52.1).

Skeletal muscle is composed of multinucleated muscle fibers containing organized units of contractile elements. Muscle contraction is the result of ATP-dependent interactions between hundreds of myosin and actin filaments in each sarcomere, which are then amplified by thousands of sarcomeres in each muscle fiber. A specialized endoplasmic reticulum (sarcoplasmic reticulum) stores calcium and allows for rapid conversion of electrical potential from a nerve impulse to a chemical signal to initiate contraction. Skeletal muscle contraction is highly adaptive to increased demand in response to exercise or load bearing. In addition, as a major protein store in the body, skeletal muscle can also respond to the metabolic activity that maintains whole-body protein homeostasis. Thus skeletal muscle can participate in several anabolic and

catabolic processes that increase or decrease in muscle mass. Muscle homeostasis is a carefully regulated balance between these anabolic and catabolic pathways and the cellular signaling that controls these processes.

The rate of whole-body protein turnover in a normal, healthy man is approximately 3.7–4.7 g of protein/kg/day, most of which are intracellular proteins [2]. The half-lives of proteins and rates of proteolysis are tightly regulated. The rate of protein turnover increases acutely in states of anorexia (starvation), inflammation, and infection, with preferential loss from the skeletal muscle such that the muscle–protein balance becomes negative, but visceral organ function is relatively preserved. Much of the amino acids released from breakdown of protein are then used for gluconeogenesis or by muscle for energy production [2]. Over time, even in the continued presence of the above disorders, protein breakdown diminishes substantially, which can be considered an adaptive response.

## Anabolic mechanisms and pathways

Mononucleated myogenic stem cells called satellite cells reside between the sarcolemma and the basal lamina in the muscle fiber and are normally quiescent in skeletal muscle of adults. However, in the setting of muscle injury, satellite cells are able to proliferate and fuse with each other and with damaged muscle fibers, contributing myonuclei to growing muscle fibers to regenerate skeletal muscle. Although satellite cells can form new satellite cells to self-replenish, their numbers decrease with age [3].

FIGURE 52.1 Major anabolic and catabolic pathways for protein that could be targeted for therapeutics.

Several molecular pathways contribute to skeletal muscle hypertrophy and regeneration. The insulin-like growth factor-1 (IGF-1)/PI3K/Akt pathway is one of the best described pathways in skeletal muscle anabolism. IGF-1 binds to its receptor (IGF-1R), which induces phosphorylation of the receptor and then recruitment of insulin receptor substrate 1 (IRS1). Subsequent stimulation of the PI3K/Akt pathway results in phosphorylation and activation of mTOR signaling. mTOR signaling translates downstream to enhance translation initiation and protein synthesis. In mouse models, activation of the Akt pathway induces muscle hypertrophy and increases skeletal muscle mass [4]. Testosterone, growth hormone (GH), and vitamin D have all been considered as potential therapeutic agents to stimulate this anabolic pathway to increase muscle mass and function (Fig. 52.1). This pathway can be inactivated when IRS1 is tagged for ubiquitin-mediated degradation by ligases such as SOCS1 and SOCS3, a link between the anabolic and catabolic pathways in muscle.

### Catabolic mechanisms and pathways

Muscle protein catabolism is a normal and routine process, and muscle wasting occurs when there is a shift such that protein degradation and proteolysis exceeds protein synthesis. The major proteolytic

pathway is through activation of caspase-3 and the ubiquitin–proteasome system (UPS) (see also Chapter 10: Metabolic and Nutritional Responses to Acidemia and Alkalemia). Ubiquitin is activated by an enzyme (E1), transferred to carrier proteins (E2), and then conjugated to the substrate protein to be degraded by a ligase (E3). This then leads to rapid degradation of the substrate protein by a proteasome [2]. Catabolism can either be triggered by catabolic signaling such as through the myostatin pathway or by a decrease in anabolic signaling. Decreased anabolic signaling through phosphorylated Akt also leads to the downstream stimulation of specific E3 ubiquitin-conjugating enzymes: atrogen-1/muscle atrophy F-box (MAFbx) and muscle ring finger 1 (MuRF1). These enzymes recognize specific muscle proteins such as myosin heavy chain and myosin-binding protein C in the sarcomere, increasing their degradation by the UPS. Myostatin negatively regulates Akt signaling and induces signaling in the MuRF1 and MAFbx pathways that results in increased catabolism.

This chapter will review major agents acting directly on muscle anabolic or catabolic pathways that have been tested in clinical trials with outcomes related to muscle mass or muscle function. However, it is important to note that there are other strategies that might affect these pathways indirectly, such as interventions to address nutrition and inflammation. Future therapeutic approaches may also involve mechanisms

involving pathways independent of classic anabolic signaling, such as targeting G-proteins, mitochondrial oxidative metabolic pathways, and muscle-specific microRNAs.

## Myostatin

Myostatin, a member of the transforming growth factor- $\beta$  (TGF- $\beta$ ) superfamily, has long been known to be an important negative regulator in skeletal muscle. The myostatin story started well before the discovery of the responsible gene, with its origin in selective cattle breeding. In 1807 a British farmer described “bovine muscular hypertrophy” in cattle with such excessive muscles they were dubbed “double muscled.” In 1997 McPherron et al. showed that muscle isolated from myostatin knockout mice weighed two to three times more than those isolated from wild-type mice. The skeletal muscle increase appeared to be mostly muscle hyperplasia with some muscle fiber hypertrophy [5]. McPherron and Lee went on to show that mutations in the myostatin coding sequence are responsible for muscle hypertrophy in the Belgian Blue and Piedmontese breeds of double-muscled cattle [6]. Myostatin is highly conserved across species, including in pigs, chickens, turkeys, baboons, and humans [6]. The importance of the myostatin gene in humans was highlighted by a case report of an infant with muscular hypertrophy. At 6 days of age the infant’s quadriceps muscle volume by ultrasound was 7.2 SD above the mean for age- and sex-matched controls. When he was 4.5 years old, the child was able to hold two 3-kg dumbbells in horizontal suspension with arms extended. This child was found to have a loss of function mutation in myostatin resulting in absence of serum myostatin propeptide [7]. Conversely, myostatin overexpression in mice leads to loss of muscle parenchyma and fat analogous to cachexia without change in nutritional intake [8].

Myostatin is first expressed as a 375-amino acid propeptide, which is then cleaved to form a latent myostatin and further processed to produce a 26-kDa active myostatin. Myostatin binds to activin receptor type IIB (ActRIIB) and with lesser affinity to activin receptor type IIA, forming a complex with the activin type I receptors (ALK 4/5). Activation of these receptors further activates SMAD2 and SMAD3 transcription factors. This leads to downstream signaling that suppresses Akt signaling and increases expression of atrogen-1 and MuRF1. These actions, in turn, enhance protein degradation by stimulating ubiquitin–proteasome activity [9]. Follistatin is a glycoprotein that binds to myostatin and inhibits binding to its receptor. Follistatin also blocks activities of other TGF- $\beta$  family

members that limit muscle mass, such as activin A [10].

Plasma myostatin concentrations appear to be higher in individuals with CKD compared to those without CKD, even in stages 1 and 2 CKD, and there is an inverse correlation between myostatin concentrations and eGFR [11]. Muscle biopsies obtained from patients with stage 5 CKD at the time of catheter insertion for peritoneal dialysis showed apoptotic loss of myonuclei, upregulated expression of myostatin and IL-6, and decreased expression of IGF-1 compared to controls. In addition, upregulation of myostatin was associated with increased IL-6 expression, suggesting a pathway by which inflammation may lead to protein catabolism and reduction of muscle mass [12]. In mouse models of CKD, injection of antimyostatin antibodies prevented the development of muscle atrophy and reversed established muscle atrophy. These outcomes occurred through suppression of inflammatory cytokines, reduction in protein degradation, increase in satellite cell function, and increase in IGF-1 signaling [13].

Myostatin inhibition is a logical target for human therapeutics to counter loss of muscle mass in CKD. However, despite the excitement surrounding preclinical data on myostatin inhibition, clinical trials of myostatin inhibitors have been met with many difficulties. Current strategies to block myostatin largely focus on using antibodies to block myostatin or its receptors, ligand traps to block myostatin from its receptor, or overexpression of follistatin as a natural inhibitor of myostatin. Here, we describe several prominent therapeutics to block myostatin or TGF- $\beta$  family signaling that have been evaluated in clinical trials (Table 52.1).

### Antimyostatin therapeutics (antibody, peptibody, or adnectin)

MYO-029 (Wyeth) was the first monoclonal antimyostatin antibody to be tested in clinical trials in humans. Although this myostatin inhibitor increased muscle mass in phase I/II trials, timed muscle testing did not improve significantly, leading to discontinuation of development of this drug. LY2495655 (Lilly) is a human monoclonal antibody against myostatin. A phase II trial in patients with cancer cachexia was terminated due to a higher death rate in the group receiving LY2495655, and another trial among patients undergoing elective arthroplasty did not meet its efficacy endpoints [14,15]. However, a study in elderly individuals with a history of falling showed that LY2495655 increased appendicular lean body mass and improved stair-climbing time, muscle power, chair rise times, and gait speed compared to the group that

TABLE 52.1 Antimyostatin therapeutics.

Drug molecule	Mechanism	Study population	Trial stage	Note
Stamulumab; MYO-029 (Wyeth)	Myostatin Ab	Muscular dystrophy	Phase II	Discontinued; failed to increase muscle strength
PF-06252616 (Pfizer)	Myostatin Ab	DMD	Phase II	Did not meet efficacy endpoints
		LGMD2I	Phase II	
Trevogrumab; REGN1033 (Regeneron)	Myostatin Ab	Sarcopenia	Phase II	
REGN1033 + REGN 2477 (garetosmab)	REGN2477: activin A, Ab	Postmenopausal women, healthy men	Phase I	Trial in progress
Landogrozumab; LY2495655 (Lilly)	Myostatin Ab	Pancreatic cancer	Phase II	Terminated due to imbalance in death rate between treatment arms
		Elderly faller	Phase II	
		Elective total hip arthroplasty	Phase II	Did not reach threshold of primary objective
PINTA-745; AMG 745 (Amgen)	Antimyostatin peptibody	End-stage renal disease	Phase II	Discontinued, due to not meeting efficacy endpoints
BMS-986089 (Bristol–Myers–Squibb)	Antimyostatin adnectin	DMD	Phase I/II	
Ramatercept ACE-031 (Acceleron)	Soluble activin type IIB R	Postmenopausal women	Phase I	Completed in 2011
		DMD	Phase I	Terminated; due to gum bleeding, nose bleed, and small dilated vessels in skin
ACE-083 (Acceleron)	Modified human follistatin, “ligand trap”	FSHD	Phase II	
		Charcot–Marie–Tooth disease	Phase II	
Bimagrumab (BYM338) (Novartis)	ActRIIA/ActRIIB Ab	sIBM	Phase IIb/III	Did not meet primary endpoints
		Sarcopenia	Phase II	Completed 2013
		Hip fracture	Phase II	
		COPD	Phase II	
		Lung and pancreatic cancer	Phase II	
AAV1.CMV.huFS344	Delivery of follistatin	BMD and sIBM	Phase I/IIa	
AAV1.CMV.huFS344	Delivery of follistatin	DMD	Phase I/II	

*Ab*, Antibody; *ActRIIA*, activin receptor type IIA; *ActRIIB*, activin receptor type IIB; *BMD*, Becker muscular dystrophy; *COPD*, chronic obstructive pulmonary disease; *DMD*, Duchenne muscular dystrophy; *FSHD*, facioscapulohumeral muscular dystrophy; *LGMD2I*, limb–girdle muscular dystrophy 2I; *sIBM*, sporadic inclusion body myositis.

received placebo [16]. There has been only one drug in clinical trials of patients with ESRD. The drug tested was PINTA 745 (Atara Bio), a myostatin-neutralizing peptide fused to an Fc domain (a myostatin peptibody). Unfortunately, development was discontinued after PINTA 745 failed to meet its efficacy endpoints in phase I/II trials [17]. A myostatin antibody, REGN1033

(Regeneron), has been evaluated for patients with sarcopenia. PF-06252616 (Pfizer) has been in phase II clinical trials in patients with Duchenne muscular dystrophy (DMD) and limb–girdle muscular dystrophy 2I. However, further trials in patients with DMD were terminated after the phase II trial failed to meet its primary efficacy endpoints. Bristol–Myers–Squibb

developed an engineered protein designed to bind with high affinity and specificity to myostatin, an anti-myostatin adnectin (BMS-986089), which is currently in phase II/III trials in ambulatory boys with DMD. Adnectins are engineered to be similar to antibodies but are more stable and easier to produce [18].

There are several potential reasons why myostatin inhibitors have not produced expected outcomes in clinical trials. Several ligands in the TGF- $\beta$  superfamily other than myostatin also participate in the signaling pathway leading to inhibition of skeletal muscle anabolism and increasing catabolism, most notably activins. Activin A appears to have a more prominent role in muscle inhibition in primates than in mice, which may help to explain why pure myostatin inhibition produces less response in human clinical trials than in preclinical trials in mice [19]. Preferentially, inhibiting signaling by myostatin may also prime the muscle to respond maximally to activation of SMAD2/3 signaling from other TGF- $\beta$  superfamily ligands, such as activins [20]. In support of this explanation, simultaneous inhibition of myostatin and activins appears to lead to a synergistic hypertrophic response [21]. As a consequence, newer drugs in development, which are described next, block multiple targets or more downstream targets of myostatin signaling.

### Activin A-based therapy

REGN2477 (Regeneron), an antibody against activin A, is combined with a myostatin blocker (REGN1033), and it is hypothesized that this combination might synergistically block two major ligands in the signaling pathway through the ActRIIB receptor. This combination approach is currently in phase I clinical trials in postmenopausal women and healthy adult men [22].

### Ligand trapping (soluble ActRIIB or follistatin based)

ACE-031 is a recombinant protein that contains part of the ActRIIB receptor fused to part of a human antibody. The result is a soluble, circulating form of ActRIIB that can interfere with myostatin binding to the endogenous ActRIIB receptor. The development of this drug was halted due to safety concerns related to epistaxis and telangiectasias that were observed in a phase II trial in patients with DMD [23]. The same company, Acceleron, has two newer drugs in clinical trials, ACE-083 and ACE-2494, that are a fusion of a version of human follistatin with an IgG Fc domain. This follistatin fusion protein binds tightly to myostatin and activins so as to “trap” these ligands and neutralize their ability to signal downstream [24].

### ActRIIB binding

A different strategy adopted by Novartis is to target the receptor in the TGF- $\beta$  pathway rather than such ligands as myostatin and activins. Bimagrumab is a human monoclonal antibody that binds ActRIIB, thereby preventing binding of myostatin with several TGF- $\beta$  family ligands. Novartis conducted several clinical trials of patients with sarcopenia, chronic obstructive pulmonary disease (Type 2 DM), sporadic inclusion body myositis (sIBM), hip fracture surgery, or cancer cachexia (lung or pancreatic). In the phase II trial among community-dwelling adults with sarcopenia, bimagrumab increased lean body mass and thigh muscle volume. In addition, the participants who received bimagrumab demonstrated improvement in grip strength, gait speed, and 6-minute walk time as compared to those receiving placebo [25].

### Follistatin overexpression

Follistatin is not only a potent myostatin inhibitor, but also it manipulates TGF- $\beta$  signaling pathways independent of its action on myostatin [26]. Using a novel approach of delivering follistatin via an adeno-associated virus vehicle, investigators have completed small proof-of-concept clinical trials in patients with Becker muscular dystrophy and sIBM with positive results. This has set the stage for larger pilot trials of follistatin delivery.

Current clinical trials continue to focus on blocking TGF- $\beta$  family ligands, but this approach faces several challenges. The specificity of the drug candidates has been difficult to achieve given the high degree of similarity among receptors of TGF- $\beta$  family members. Pharmaceutical inhibition of myostatin has led to muscle hypertrophy [27], whereas hyperplasia is the mechanism by which muscle size increases in myostatin knockout models, and this may be one reason several clinical trials have achieved increases in muscle mass without improvement in muscle function. Also, several clinical trials have been conducted in people with chronic neuromuscular diseases; an increase in their muscle mass without the appropriate increase in innervation of these muscles may limit the improvement in muscle function. More clinical trials of CKD and ESRD patients are needed to examine whether these same problems impair drug effectiveness in these populations.

Currently, most antimyostatin antibodies have targeted the mature form of myostatin. However, newer strategies are focusing on promyostatin and latent myostatin. These proteins may be more specific and may have a more durable effect, since latent myostatin is the predominant form of myostatin in circulation,

and promyostatin is the predominant form in the muscle. Antibodies targeting promyostatin are still in pre-clinical phases of investigation at this time [28].

### GH and IGF-1

GH is secreted in a pulsatile fashion from the pituitary gland in response to signaling from GH-releasing hormone. This release is inhibited by somatostatin. Other nutritional hormones such as insulin and ghrelin also play a role in regulating GH release. Most of the anabolic actions of GH are related to the stimulation of IGF-1. IGF-1 is a 70-amino acid peptide produced in the liver and locally in GH-stimulated tissues. In circulation, IGF-1 is largely protein bound to IGF-binding proteins (IGFBP-1–6) and especially to IGFBP-3. IGF-1 signaling is important in skeletal muscle homeostasis since it activates anabolic signals and inhibits catabolic signals by activating the PI3K/Akt pathway (Fig. 52.1). IGF-1 also inhibits muscle catabolism by inhibiting expression of MuRF1 and Atrogin-1 [29]. In adult mice a decrease in IGF-1 signaling leads to a decrease in anabolic signals but to no change in catabolic signals, tilting the balance toward muscle atrophy [29]. Conversely, overexpression of IGF-1 in mouse skeletal muscle leads to myofiber hypertrophy [30].

GH also has direct, rapid onset effects on protein metabolism. The mechanisms of these actions are less well understood; however, the rapidity of these metabolic actions suggests that they are independent of signaling through IGF-1. It is thought that one of the direct actions of GH on tissue is to stimulate incorporation of amino acids into protein [31]. In one study, rodents that have undergone hypophysectomy undergo a loss in type I and type II muscle fibers. Replacement of GH reverses this loss of muscle fiber [32,33]. There are also opposing data showing no change in muscle fibers with GH replacement [34].

GH has long been used as an anabolic and performance-enhancing agent in competitive sports in humans. However, until the 1990s, there were limited data from clinical trials supporting its effectiveness. In one of the trials establishing GH as an anabolic hormone, 12 men with hypopituitarism treated with GH for 6 weeks showed increases in whole-body protein synthesis [35]. GH was also shown to counteract corticosteroid-induced protein catabolism [36]. These results were confirmed in adults with GH deficiency [37]. However, this increase in protein synthesis did not always translate into increases in muscle fiber area [38–40]. GH may also improve muscle function in other ways, such as by increasing aerobic exercise capacity by increasing red cell mass and thereby increasing oxygen delivery to muscle [41–43]. In a

clinical trial in older healthy adults, participants who were 61–81 years old were randomized to receive placebo or biosynthetic GH injections three times a week for 6 months. Those who received GH showed an increase of 3.7 kg (0.7–6.6 kg) in lean body mass [44]. However, despite the increase in lean body mass, a subsequent study did not show that GH improved physical function as measured by knee or hand-grip strength [45].

CKD has been described as a state of GH resistance rather than deficiency, which complicates efforts to restore the GH axis because higher doses of exogenous GH would be needed. There are several possible mechanisms leading to a disturbed GH/IGF-1 axis in renal failure. Most investigators have found normal serum IGF-1 levels in individuals with CKD, perhaps due to decreased clearance of GH combined with increased feedback at the pituitary. However, observations that hepatic GH receptor gene expression is lower in chronically uremic states than among healthy individuals [46] suggest GH resistance. Also, IGF-binding protein concentrations are increased in CKD, limiting the bioavailability of circulating IGF-1 [47]. Finally, uremic rats treated with IGF-1 demonstrated less response as measured by increase in protein synthesis and decrease in protein catabolism as compared with control rats, suggesting IGF-1 resistance in CKD [48]. IGF-1 is not removed during hemodialysis because of its size and the fact that it is largely protein bound.

There have been small clinical trials in chronic dialysis patients examining the use of recombinant GH or IGF-1. In an early study in six maintenance hemodialysis (MHD) patients, recombinant human GH (rhGH) was administered for 6 weeks in a crossover study. The authors showed that rhGH administration led to an increase in muscle protein synthesis and a decrease in negative muscle protein balance as measured by phenylalanine balance [49]. Another trial randomized 21 MHD patients in Denmark to treatment with GH for 6 months versus placebo. The authors found that in the GH treated group, lean body mass as measured by DEXA increased by  $3.0 \pm 0.75$  kg compared to  $1.03 \pm 0.45$  kg in the placebo group [50]. The largest clinical trial designed to investigate whether GH improves muscle mass and strength among MHD patients was The Effect of Somatropin Treatment in Adult Patients on Chronic Dialysis (OPPORTUNITY) trial. Investigators had planned to enroll 2500 patients randomized to placebo or injections of recombinant GH for a duration of 24 months, but unfortunately, the trial was terminated early due to slow recruitment, and the patients who were recruited were followed for a shorter period of time, resulting in lower statistical power. There was no detectable change in lean body

mass or exercise capacity comparing those who received GH with those who received placebo. There was, however, a decrease in total body fat and hs-CRP in those receiving GH [51].

In light of this experience, the future use of GH to stimulate anabolic effects in CKD is uncertain. Barriers include the short half-life of GH and IGF-1 and continuing uncertainty about their efficacy. Sustained-release formulations of both rhGH and IGF-1 have been tested in clinical trials among GH-deficient pediatric patients, but they have not been studied in patients with CKD. A concern of these longer lasting preparations is that clearance of GH is already reduced in the setting of CKD. Recombinant IGF-1 injections have been tested in patients with neuromuscular diseases, but results from these trials have been disappointing, showing a lack of change in muscle volume [52] and muscle function [53]. There are also lingering concerns about potential adverse effects of GH on cardiovascular risk. Patients with acromegaly from chronic excess GH exposure are at risk for hypertension, ventricular hypertrophy, cardiac valve disease, arterial intima-media thickness, and arrhythmias.

Data supporting caution with the use of therapeutic GH come from a published study with data from two randomized multicenter placebo-controlled trials conducted in parallel in Europe. Patients in the intensive care unit were randomized to rhGH or placebo, and although the patients treated with rhGH had improved nitrogen balance, hand-grip strength was unaffected. In addition, patients treated with rhGH had a higher mortality rate and longer hospitalization compared to those in the placebo group [54]. These studies were done in critically ill populations and may not be generalizable to those who are less ill. Furthermore, the reason for increased morbidity and mortality in this study is still unclear. Possible mechanisms include fluid retention, hyperglycemia, and higher rhGH dosing due to patients being in a hypercatabolic and GH-resistant state, and these mechanisms are potentially relevant in determining a therapeutic window for GH use in CKD.

Finally, other promising methods for increasing the bioavailability of IGF-1 are emerging and may be promising in states of GH resistance such as CKD. These include the use of small molecules to block IGF-1 from binding to its binding proteins or to displace it from binding proteins once bound. The development of these molecules is currently limited to preclinical trials.

## Vitamin D

Vitamin D was discovered in 1919 by Sir Edward Mellanby, who induced rickets in dogs that were kept

indoors. He noticed that rickets was cured with cod liver oil and thought the effect was due to vitamin A. However, in 1922, it was discovered that cod liver oil treated by heat to destroy vitamin A still cured rickets, and thus another substance must be responsible. The new substance was named with the next available letter in the alphabet and called "vitamin D" [55,56].

The formation of vitamin D begins in the skin where UV radiation drives the conversion of 7-dehydrocholesterol to cholecalciferol (vitamin D<sub>3</sub>). Vitamin D<sub>3</sub> circulates largely bound to vitamin D-binding protein and is transported to the liver where 25-hydroxyvitamin D (25OHD) is generated. 25OHD next undergoes 1  $\alpha$ -hydroxylation in the proximal tubules of the kidney, which is the rate-limiting step in the synthesis of the most active form of vitamin D, 1,25-dihydroxycholecalciferol (1,25-(OH)<sub>2</sub>D) [57] (Fig. 52.2). Finally, 1,25-(OH)<sub>2</sub>D is inactivated by 24-hydroxylase, an enzyme that also converts 25OHD to 24,25(OH)<sub>2</sub>D, an inactive metabolite. Several molecules and hormones interact in the regulation of 1  $\alpha$ -hydroxylase activity to synthesize active vitamin D, including calcium, parathyroid hormone, calcitonin, GH, IGF-1, and fibroblast growth factor-23 (FGF-23) [58] (please also see Chapters 23, 24, and 25).

## Mechanism of vitamin D action in muscle

The influence of vitamin D on calcium, phosphorus and the maintenance of normal skeletal development has long been established. Vitamin D also affects skeletal muscle at the cellular level. 1,25-(OH)<sub>2</sub>D binds to the vitamin D receptor (VDR), which then binds to the nuclear receptor retinoid X receptors (RXRs) to modify gene transcription. These genomic effects are thought to increase expression of contractile proteins and myogenic transcription factors and to enhance differentiation of myoblasts into myotubes [57,59,60]. The nongenomic response to vitamin D involves activation of multiple cell signaling pathways, including cyclic adenosine monophosphate, protein kinase A, protein kinase C, protein kinase B/Akt, and extracellular signal-regulated kinase (ERK1/2). These pathways lead to rapid calcium influx into myocytes. This calcium signaling plays a role in myocyte contractile function by regulating muscle contractile proteins such as actin, myosin, and troponin C [57] (Fig. 52.3). In addition, vitamin D influences myocyte proliferation and differentiation [61], in part by influencing the fate of mesenchymal stem cells to promote myogenesis and inhibit fibrosis [62]. In vivo data in rats also suggest that vitamin D increases muscle cell proliferation and decreases apoptosis after trauma [63].

## Vitamin D deficiency and muscle function

VDR knockout mice develop atrophy of muscle fibers leading to significant impairment in motor performance [64]. There has been intense debate for many years over whether the VDR is expressed in human skeletal muscle; however, most experts now agree that VDR is expressed in skeletal muscle, albeit at very low levels [60,65,66]. Supporting the role of VDR in muscle is the observation that muscle atrophy is observed in individuals with VDR mutations even before they develop osteomalacia [67,68].

## Clinical trials in the general population

Human rickets and osteomalacia have long been characterized by muscle weakness, particularly in proximal muscles [69]. Based on long-term observations of an association between myopathy and osteomalacia, there has been considerable interest in whether vitamin D supplementation could improve muscle strength and function. In older adults with sarcopenia, supplementation with 800 IU vitamin D and whey protein led to improvement in muscle mass and lower limb function [70]. In another randomized trial in older women with a baseline 25OHD level under 60 nmol/L (24 ng/mL), supplementation with 1000 IU/day of ergocalciferol was associated with improvement in physical performance as measured by timed up-and-go [71]. However, in another trial in which older women with 25OHD levels <30 ng/mL were treated with 800 IU cholecalciferol daily or 50,000 IU cholecalciferol twice-monthly to increase the 25OHD to  $\geq 30$  ng/mL or with placebo, muscle function, as measured by timed-up-and-go and sit-to-stand tests, did not improve significantly in any of the treatment arms [72]. Since the effects of vitamin D supplementation on muscle function have been mixed, a metaanalysis of 17 RCTs was performed. The results indicated that vitamin D supplements were only effective in improving muscle strength in individuals who were vitamin D deficient (as defined by serum 25OHD <25 nmol/L or <10 ng/mL) at enrollment [73]. This metaanalysis highlights the importance of selection of appropriate individuals for vitamin D supplementation.

## Vitamin D and muscle in CKD

### 25OHD and 1,25-(OH)<sub>2</sub>D deficiency in CKD

Both 25OHD and 1,25-(OH)<sub>2</sub>D levels may decrease with declining kidney function. The kidney is the main site of conversion of 25OHD to 1,25-(OH)<sub>2</sub>D. Thus as renal mass and function decrease, levels of 1,25-(OH)<sub>2</sub>D as well as 25OHD decrease in CKD.

Complicating this altered milieu, several factors interfere with 1,25-(OH)<sub>2</sub>D actions in renal failure. In addition to decreased serum 1,25-(OH)<sub>2</sub>D concentrations, there is also a reduction in expression of the VDR in the parathyroid gland, which may lead to vitamin D resistance in CKD [74]. Studies in nephrectomized rats indicate there is also decreased nuclear receptor RXRs expression leading to decreased formation of the VDR/RXR complex and impaired DNA binding and transcriptional signaling. Serum FGF-23 rises early as CKD develops and increases the activity of 24-hydroxylase, which in turn hydroxylates 1,25-(OH)<sub>2</sub>D and 25OHD to inactive forms [75]. In mice with elevated serum FGF-23 levels, administering antibodies to neutralize FGF-23 led to increased 1,25-(OH)<sub>2</sub>D concentrations and also to increased grip strength and spontaneous movement [76].

In addition to deficiency and resistance to 1,25-(OH)<sub>2</sub>D, there is also a high prevalence of 25OHD deficiency in individuals with CKD [77,78]. A cross-sectional study in the United States showed that the prevalence of 25OHD insufficiency (serum 25OHD, 10–30 ng/mL) was 57% and 58% among those with CKD stages 3 and 4, respectively, and the prevalence of 25OHD deficiency (serum 25OHD, <10 ng/mL) was 14% and 26%, respectively [77]. These rates of insufficiency and deficiency are considerably higher than the prevalence rates in the general population, which range from 27% to 50% according to data from the Third National Health and Nutrition Examination Survey (NHANES) [45]. The physiological mechanisms causing decreased serum 25OHD in CKD are less well established than those of 1,25-(OH)<sub>2</sub>D. There is some evidence that decreased reabsorption of filtered 25OHD in the renal proximal tubule [79] and decreased production of cholecalciferol in skin of CKD patients may play a role. Loss of muscle mass and decreased physical activity that accompany CKD may contribute to 25OHD deficiency because the skeletal muscle itself is important in the storage and maintenance of 25OHD levels when the availability of vitamin D is low [80]. Higher amounts of physical activity (even indoor exercise) are also positively associated with vitamin D status [81,82]. Therefore there might be a spiral wherein low vitamin D contributes to decreased physical function and muscle mass, which decreases ability to store vitamin D, which then further reduces muscle mass.

### Relative importance of 25OHD and 1,25-(OH)<sub>2</sub>D for preservation of muscle mass and function in CKD

Whether repletion of 25OHD, in addition to active 1,25-(OH)<sub>2</sub>D, suppresses hyperparathyroidism, increases

survival, or improves mineral metabolism in advanced, nondialyzed CKD patients or ESRD patients is controversial [83–85]. It is also unclear whether the vitamin D actions on the skeletal muscle in advanced CKD patients is dependent entirely on 1,25-(OH)<sub>2</sub>D or whether 25OHD also contributes to these processes. Although the VDR in skeletal myocytes has a 500- to 1000-fold greater affinity for 1,25-(OH)<sub>2</sub>D as compared to 25OHD, there is an approximately 500-fold higher concentration of 25OHD in skeletal muscle [86]. Investigations addressing the relative effects of 25OHD and 1,25-(OH)<sub>2</sub>D have been limited to observational studies and very small randomized trials with short durations of treatment; hence, there are insufficient data to compare the effects of 25OHD versus 1,25-(OH)<sub>2</sub>D on muscle.

### Observational studies

Observational studies in advanced CKD patients and MHD patients show an inverse association between serum 25OHD concentrations and lean body mass and muscle cross-sectional area [87,88]. A study using the Korean NHANES data indicated a higher prevalence of sarcopenia in participants with CKD and 25OHD deficiency (defined as serum 25OHD <20 ng/mL) as compared to those with CKD without 25OHD deficiency [89]. MHD patients who were receiving 1,25-(OH)<sub>2</sub>D also had higher muscle strength, as measured by isokinetic strength of knee extensors and isometric strength of ankle dorsiflexors, than those not receiving 1,25-(OH)<sub>2</sub>D, but there was no significant difference in physical performance as measured by gait speed, stair climb, sit-to-stand time, or get-up-and-go time [90]. However, Gordon et al. found that serum concentrations of both 25OHD and 1,25-(OH)<sub>2</sub>D were directly correlated with gait speed in patients with stages 3 and 4 CKD [87]. Boudville et al. found that serum 25OHD concentrations, but not serum 1,25-(OH)<sub>2</sub>D levels, correlated with isometric quadriceps strength in MHD patients [91].

### Interventional studies

Interventional studies of supplemental 25OHD and 1,25-(OH)<sub>2</sub>D in CKD have mainly focused on the effects on hyperparathyroidism, renal osteodystrophy, and mineral metabolism. Few clinical trials have the effects on explored muscle mass or function, and the results have been conflicting. In a small clinical trial of 52 participants, Marckmann et al. treated nondialyzed advanced CKD patients and MHD patients with 40,000 IU cholecalciferol per day for 8 weeks. Compared with those treated with placebo, participants treated with cholecalciferol did not achieve

significant improvement in muscle function as measured by the weight lifted by the dominant arm and sit-to-stand testing at 8 weeks [92]. Hewitt et al. completed a similar trial in 60 MHD patients with a longer treatment time of 6 months. Although baseline serum 25OHD concentrations correlated with distance in the 6-minute walk test, there were no significant changes in grip strength, elbow, hip, and knee extension/flexion strength, or functional tests, including repeated chair stand, postural stability, and 6-minute walk distance after 6 months of cholecalciferol supplements [93]. However, in another trial of 25 patients with CKD stages 3–4 and 50 chronic peritoneal dialysis patients, supplements of 50,000 IU cholecalciferol given once-weekly for 4–8 weeks resulted in a significant increase in isokinetic strength of the flexor and extensor muscles of the knee. There was no significant difference between the cholecalciferol versus placebo treatment groups in muscle function as measured by timed repeated chair standing, stair climb, or gait velocity [94]. Lack of statistical power, different durations of treatment, and publication bias are possible explanations for these conflicting results with regard to changes in muscle strength and function, although it is notable that the longer study did not report more benefits than the studies of shorter duration. It is noteworthy that none of these trials used 1,25-(OH)<sub>2</sub>D as the form of vitamin D supplementation, so it is still unclear whether 1,25-(OH)<sub>2</sub>D might be more effective at improving muscle function.

The 2020 KDOQI Clinical Practice Guidelines for Nutrition in CKD recommend vitamin D supplementation in the form of cholecalciferol or ergocalciferol in CKD stages 1–5D to correct 25OHD deficiency or insufficiency [95]. In adults with CKD with nephrotic range proteinuria, the guidelines recommend consideration of supplementation of cholecalciferol or ergocalciferol. The guidelines do not explicitly address whether supplementation with cholecalciferol, calcitriol, or a combination of both would result in benefits to muscle strength or function in CKD patients. Larger randomized trials are needed to determine whether the dosage, length of supplementation, or type of vitamin D compound will influence the effects of vitamin D on muscle strength and function. Studies from the general population have shown that high doses of vitamin D may actually increase fall risk [96], and in the CKD population, there continues to be concern regarding excess vitamin D contributing to vascular calcification [97].

---

### Testosterone

Although the name testosterone was only coined in 1935, it has long been theorized to have benefits for

improving well-being. In 1889 Brown-Sequard published results of his self-experimentation and described “rejuvenation by testicular extracts” [98]. Other physicians followed, with reports describing that testicular extracts “increased capacity of work considerably above that which would follow exercise alone.” Brown-Sequard’s observations may have been overstated, as modern scientists have repeated the extraction of hormones from dog testes using the Brown-Sequard method and found that his injections would have contained only approximately 100 ng of testosterone; the testes do not store testosterone in large concentrations even though they are the site of testosterone synthesis. These scientists who could not replicate Brown-Sequard’s results concluded that “the placebo effect can be powerful, even in a highly educated physician” [99]. The androgenic substance named testosterone was finally isolated from bull testes by Ernst Laqueur in 1935. Subsequently, in 1939, Adolf Butenandt and Leopold Ruzicka were awarded the Nobel Prize for the synthesis of testosterone, thus jump-starting the field of therapeutic testosterone for increasing muscle size and strength.

### Mechanism of testosterone’s anabolic effects on muscle

Testosterone induces muscle fiber hypertrophy by several mechanisms, tipping the balance of protein synthesis and breakdown toward net anabolism. Evidence suggests that testosterone increases protein synthesis in skeletal muscle without increasing intracellular amino acid transport by reusing amino acids generated from protein breakdown for synthesizing new protein. Testosterone may also decrease the amount of protein catabolism that occurs during fasting [100–102]. In addition, testosterone has been shown to increase the number of satellite cells, the precursor to new myocytes, in the muscle in a dose-dependent manner. Therefore testosterone can increase skeletal muscle mass not only by myofiber hypertrophy but also by increasing myoblast differentiation.

Testosterone acts directly through the androgen receptor with both genomic and nongenomic effects. Genomic effects of testosterone stimulate myogenic differentiation while inhibiting adipogenic differentiation [103]. Nongenomic effects of testosterone activate a cascade of intracellular calcium release and the Ras/MEK/ERK1/2 pathway [104]. Outside of the myoblast, motor neurons are also dependent on androgens. In castrated animals, motor neurons decrease in size [105]. But when these animals are treated with testosterone, their motor neurons increase in number [106]. Finally, in addition to exerting positive regulation on

muscle growth, testosterone also inhibits the transcription of myostatin in rats [107].

### Clinical trials in the general population of the effects of testosterone on muscle mass and muscle function

The use and abuse of anabolic and androgenic substances for increasing muscle size and strength was prevalent even before there were high-quality data showing their efficacy in humans. Despite the long-heralded anecdotal effects of testosterone on muscle among athletes, the scientific data on the anabolic effects of testosterone were controversial for many decades. However, starting in the late 1990s, there was a surge in clinical trials of different testosterone formulations that explored the effects on muscle mass and strength. Bhasin et al. were the first to show that testosterone injections, at supraphysiological doses, increased fat-free mass, muscle size (as measured by triceps and quadriceps area), and muscle strength (as measured by bench-press and squatting-exercise) in a linear fashion [108]. Testosterone was then also shown to increase lean mass in hypogonadal men [101,109,110], in older men with low-normal testosterone [111,112], and in men with HIV [113–115].

Although testosterone has been consistently shown to increase muscle size, whether it also improves physical function has remained more controversial. The Testosterone in Older Men with Mobility Limitations (TOM) trial was a randomized controlled trial designed to determine if testosterone gel increased lower extremity strength in men ages 65 and older. The trial was stopped early in 2009 when the data and safety monitoring board found more adverse cardiovascular events occurred in the testosterone group than in the placebo group [116]. (Cardiovascular complications of testosterone treatment will be discussed in more detail later in this chapter.) However, in 2016, Snyder et al. published results from 790 men who participated in The Testosterone Trials, a coordinated set of smaller trials that included the Sexual Function Trial, Physical Function Trial, and the Vitality Trial. In the Physical Function Trial the primary outcome was distance walked in 6 minutes, and the secondary outcome included the Physical Function score (PF-10) of the Medical Outcomes Study 36-Item Short-Form Health Survey. Although there was no significant difference in 6-minute walk distance in the cohort enrolled in the Physical Function Trial, there was a significant increase in the PF-10 score among those treated with testosterone compared with those who received placebo. When combining all testosterone trial participants, there was a significant increase in 6-minute walk distance and PF-10 score [117].

## Testosterone in CKD and ESRD

Serum testosterone decreases with age and chronic illness, and the prevalence of testosterone deficiency is higher in men with ESRD (44% in a Swedish cohort) than in healthy men of similar age (5.6%–9.5%) [118,119]. The precise mechanisms leading to the disruption of the hypothalamic–pituitary–gonadal axis in patients with CKD and ESRD are still unclear. Several possible mechanisms include (1) disruption in gonadotropin-releasing hormone by the hypothalamus leading to a decreased pulsatile release of luteinizing hormone (LH) by the pituitary gland; (2) hyperprolactinemia and elevated serum LH levels from reduced renal clearance, producing a negative feedback on the hypothalamus [120]; (3) increased sensitivity in the pituitary to the negative feedback from testosterone itself [121]; and (4) testicular failure in CKD due to possible inhibitors to LH receptor signaling [122], abnormal testicular histology with impaired germinal and Leydig cell function, and low testicular volume [123].

In patients with ESRD, Carrero et al. showed that men with low serum testosterone concentrations (in the lowest tertile) had a 2.03-fold higher hazard ratio (1.24–3.31) for all-cause mortality as compared with the nonlow testosterone group (i.e., the highest and middle tertiles) [124]. As in the general population, there is evidence that serum testosterone and muscle mass are closely associated in patients with advanced CKD and ESRD; but evidence is still unclear to what extent serum testosterone affects physical function in CKD and ESRD patients. Observational studies of people with CKD and ESRD found that lower serum testosterone concentrations were associated with reduced muscle mass and fat-free mass, as estimated by bioelectrical impedance vector analysis [125], computed tomography [126], and serum creatinine (sCr) levels [124].

These observational studies have been confirmed by several small interventional trials. The first such study of androgen therapy in the dialysis population was a small 6-month randomized controlled trial of the synthetic testosterone derivative nandrolone decanoate. Patients who received nandrolone demonstrated increased lean body mass and a decrease in walk and stair-climbing time as compared with those who received placebo [127]. Subsequently, a larger  $2 \times 2$  factorial trial of nandrolone decanoate and lower extremity resistance exercise training for 3 months was conducted in 79 MHD patients. In contrast to the earlier study, although resistance exercise training resulted in increased lower extremity strength, nandrolone treatment did not. One possible explanation for the lack of measurable change in physical function with nandrolone decanoate was the shorter duration of treatment in this study [128]. In another study in MHD

patients, treatment with oxymetholone increased fat-free mass and type I muscle fiber cross-sectional area. These investigators also observed an improvement in handgrip strength and self-reported physical function scores [129].

No long-term interventional studies with androgenic agents have been conducted, but recent observational studies have examined longitudinal associations of serum testosterone with body composition and physical performance. In a retrospective longitudinal study with 440 men receiving MHD, investigators studied the change in serum testosterone concentrations, muscle mass, and physical function over 1 year [17]. Serum-free testosterone levels were associated with muscle mass (estimated by sCr and by bioelectrical impedance spectroscopy) and several measures of physical performance. In addition, lower serum-free testosterone was associated with higher odds of being frail at baseline, of becoming frail over 12 months (as defined by the Fried Frailty phenotype [130]), and of having sarcopenia. Of the frailty criteria in the Fried phenotype, serum-free testosterone concentration was specifically associated with grip strength and gait speed at baseline and over 12 months [17]. A long-term randomized clinical trial in advanced CKD and ESRD patients, similar to The Testosterone Trial, is needed to confirm the results of these observational and smaller randomized trials: that testosterone replacement increases lean body and muscle mass and may increase physical function.

## Clinician guide to treating hypogonadism

Because treatment of hypogonadism is an available option that might increase muscle mass among men with advanced CKD or who are undergoing chronic dialysis, we will discuss its diagnosis and management.

## Diagnosis of hypogonadism

Serum testosterone levels are highest in the morning and decrease throughout the day. More than 95% of testosterone circulates bound to sex hormone-binding globulin (SHBG), and a small proportion is weakly bound to albumin. The free testosterone is the unbound fraction, and biologically active testosterone consists of free testosterone and the proportion of testosterone that is weakly bound to albumin. Several factors affect SHBG concentrations in advanced CKD and chronic dialysis patients, including diabetes, obesity, and older age, and thus serum total testosterone may give a false estimation of biologically active testosterone at the tissue level. Bioactive testosterone is difficult and expensive to measure commercially, and there is wide variability between

laboratory assays and the normal ranges. Therefore serum-free testosterone may be the best clinically available measure to estimate biological activity of testosterone in advanced CKD and chronic dialysis patients. It is noteworthy that many serum-free testosterone immunoassays are inaccurate and unreliable, and there is substantial variability of results among different assays. The gold standard is measurement of free testosterone by equilibrium dialysis and liquid chromatography/mass spectrometry [131]. However, in practice, serum-free testosterone can be estimated based on measures of total testosterone and SHBG.

Serum testosterone and SHBG measurements should be obtained in the morning from a fasting blood sample, and at least two measurements on separate days should be obtained to confirm hypogonadism. The lower limit of serum normal testosterone for the assay used determines hypogonadism; for most assays, this is around 200–400 ng/dL. Most of the limits for the normal range of serum testosterone are set by the values from healthy, nonobese young men, and there are currently no standardized age-stratified normal testosterone levels. If hypogonadism is confirmed, serum LH, follicle-stimulating hormone (FSH), and prolactin should also be measured. In advanced CKD and ESRD patients, serum LH and FSH tend to be high. However, high serum LH and FSH may also point to other primary sources of hypogonadism, such as Klinefelter syndrome or cryptorchidism, and the

clinical history may help to differentiate between these causes. If serum LH and FSH are low or low normal with a serum total testosterone that is <100 ng/dL, an endocrinology evaluation is recommended to rule out pituitary adenoma as a cause of hypogonadism.

## Treatment of hypogonadism

The Endocrine Society recommends against giving testosterone therapeutically to men who are planning to reproduce or who have a serum prostate-specific antigen (PSA) level >4 ng/mL or a PSA level >3 ng/mL and a high risk of prostate cancer. Other contraindications to testosterone replacement include elevated hemoglobin, thrombophilia, untreated obstructive sleep apnea (OSA), severe lower urinary tract symptoms related to benign prostatic hyperplasia, uncontrolled heart failure, or a myocardial infarction or cerebral vascular event within the previous 6 months.

## Testosterone formulations

Formulations of testosterone have improved greatly over the last several decades. The most commonly used and most cost-effective formulations currently are transdermal and injectable testosterone (Table 52.2). Testosterone replacement does not have to be dose adjusted in the setting of CKD or chronic dialysis.

TABLE 52.2 Testosterone formulations available in the United States.

Testosterone formulation	Typical starting dose	Advantages	Disadvantages
Testosterone cypionate	150 mg IM every 2 weeks or 75 mg weekly	Widely available and affordable	Peak and trough concentrations in testosterone may produce fluctuations in symptoms
Testosterone gel (AndroGel, Fortesta, Vogelxo, Testim)	AndroGel: [1%: two 25 mg packets daily; 1.62%: 1 pump (20.25 mg) daily]	Less fluctuation in testosterone concentration. Less skin sensitivity than patch	Variation in absorption due to skin and environmental factors. Potential transfer from skin-to-skin contact
Testosterone Axillary Topical Solution (Axiron)	30–60 mg applied to the axilla daily	Less fluctuations in testosterone level. Less skin sensitivity than patch	Variation in absorption due to skin and environmental factors. Potential transfer from skin-to-skin contact. Expensive
Transdermal Testosterone patch (Androderm)	2–4 mg patch applied every 24 h	Less fluctuations in testosterone level. Easy to apply. Affordable	Skin irritation is common. May need multiple patches to achieve normal range
Buccal Testosterone (Striant)	30 mg applied to gums BID	Convenient. Steady testosterone levels	Gum-related adverse events. Expensive
Nasal Testosterone (Natesto)	11 mg (1 actuation per nostril) TID	Noninvasive. Less risk of unintentional transfer to others. Avoids first-pass metabolism	TID dosing. Expensive. Nasal adverse events
Oral testosterone undecanoate (Jatenzo)	237 mg BID	Bypasses first-pass metabolism	Bioavailability differs according to fat content in meals. Variable testosterone concentration
Testosterone pellets	600–1200 mg implanted subcutaneously	Sustained release for 3–6 months	Requires surgical incision

IM, Intramuscular; TID, three times a day; BID: twice a day.

## Safety and monitoring

Testosterone administration is associated with erythrocytosis in a dose-dependent manner, although this may be a more beneficial effect than harmful in advanced CKD and chronic dialysis patients because of the prevalence of anemia in this population. Androgen receptor signaling is also important for the growth of prostate cancer and continues to be a concern for people receiving testosterone supplements. However, there is currently no strong evidence to suggest that testosterone administration increases the risk of prostate cancer. Testosterone increases PSA levels, and many older men may have small undiagnosed prostate cancer prior to treatment that may become clinically overt during testosterone treatment due to increased surveillance [132,133]. OSA can worsen during testosterone therapy, possibly due to depression of the hypercapnic ventilatory drive [133].

Cardiovascular events are of concern as the chronic dialysis population carries a higher risk of cardiovascular disease than the general population for these events. However, the risk of mortality and adverse cardiovascular events with testosterone use continues to be controversial because of contradictory data. Small randomized trials have demonstrated that testosterone administration decreased exercise-induced myocardial ischemia [134] and chronic stable angina [135]. Two large observational studies published by Shores et al. showed that veterans with low serum testosterone ( $\leq 250$  ng/dL) had a higher hazard of all-cause mortality than those with normal serum testosterone concentrations [136]. Furthermore, those treated with testosterone had a lower risk of death compared with untreated men [137]. However, the TOM trial was discontinued due to a higher rate of cardiovascular events among participants receiving testosterone [116]. Participants in the TOM trial who had cardiovascular events also had a larger increase in their serum testosterone than those who did not [116]. Vigen et al. conducted a large observational study to examine the association between testosterone and major adverse cardiovascular events (MACE) and found that testosterone therapy was associated with a higher risk of adverse outcomes (HR 1.29; 95% CI, 1.04–1.58) [138]. Published criticisms of this study have focused on the low rate of MACE, short duration of therapy, and lack of confirmation concerning the adherence of participants to the prescribed dose of testosterone [139]. Subsequently, The Testosterone Trial did not show any difference in MACE rates between the treatment and placebo groups [117]. In men receiving chronic dialysis, Carrero et al. reported that serum testosterone concentrations were *inversely* correlated with cardiovascular-related mortality [140]. It is uncertain

how the data on cardiovascular risk in the general population would translate to men with advanced CKD or ESRD. Therefore large clinical trials in this population would be needed to fully address this question.

Monitoring during testosterone replacement therapy consists of measuring serum testosterone (usually 1 month after initiation), a hemoglobin or hematocrit level (usually around 3 months), and a yearly serum PSA level. Serum for testosterone measurement during treatment can be obtained at any time, since the timing and formulation of testosterone administration determines the serum levels more than the natural circadian rhythm. Clinicians should aim to maintain serum testosterone in the midnormal range for healthy young men. If the PSA increases by more than 1.4 ng/mL from the baseline concentration or rises to a level above 4.0 ng/mL, a urological consultation is warranted.

## Future directions

The future of androgenic therapy will probably include further development of selective androgen receptor modulators (SARMs) and clinical trials to test these agents. SARMs are an attractive way to separate the androgenic properties from the anabolic properties of androgenic substances. The mechanism by which SARMs can achieve specificity of action in tissues remains poorly understood. SARMs are formed by adding or substituting chemical groups to testosterone. One potential way to change the specificity of testosterone is by the addition of alkyl groups to the testosterone compound which then changes how the resulting androgen compound interacts with 5  $\alpha$ -reductase. The enzyme 5  $\alpha$ -reductase, which is highly expressed in the prostate gland but not in skeletal muscle, converts testosterone to dihydrotestosterone, which is a more potent androgen in the prostate. Therefore molecules that make the androgenic compound less susceptible to 5  $\alpha$ -reductase can retain anabolic activity in the muscle but have lower androgenic activity in the prostate [141]. It is also thought that the chemical scaffolds used in SARMs could induce conformational changes in the androgen receptor leading to its association with different coactivators which could then result in tissue-specific gene regulation [141]. In preclinical trials, SARMs have been shown to increase the weight of levator ani muscles in rats [142]. The development of SARMs for human use has been slow. Several compounds have been abandoned due to toxicity or lack of efficacy, but considerable effort is underway to improve the safety and efficacy of these compounds. The drug that has progressed farthest in

clinical trials is enobosarm (Gtx Inc), which was shown to increase lean body mass and physical function as measured by stair climbing in healthy elderly men and postmenopausal women in phase II trials [143]. Phase III trials in several cancer populations are ongoing.

In patients with end-stage renal disease (ESRD), regular physical exercise can be considered a cornerstone for the treatment of uremic myopathy and possibly concomitant cardiovascular disturbances [1–3]. Resistance training in these patients is reported to increase strength, functional capacity, and muscle size [4–6]. Endurance training increases functional capacity, also referred to as aerobic capacity; in some studies, endurance training is reported to ameliorate hypertension, reduce sympathetic overactivity, decrease the incidence of arrhythmias and heart rate variability, and improve health-related quality of life [7–9]. The combination of resistance and endurance training appears to be particularly effective [10–12]. Physical exercise also may exert antiinflammatory effects with lowering of the serum inflammatory markers, C-reactive protein and interleukin 6 [13,14]. However, many patients with ESRD are unable or unwilling to perform conventional exercise programs [15]. Two alternative methods for attaining the benefits of active physical exercise are neuromuscular electrical stimulation (NMES) and whole-body vibration (WBV) training.

## Neuromuscular electrical stimulation

NMES induces muscle contractions by electrical impulses that are delivered to the muscles through electrodes placed on the skin. NMES is frequently used for strength training in healthy subjects and

athletes. In animal models and human studies, increased muscle mass and muscle function have been achieved with NMES [16–18]. Strong evidence for improving impaired muscle function by NMES was observed in various chronic diseases, including heart failure [19,20], chronic obstructive pulmonary disease (COPD) [21], spinal cord injury [22], critically ill patients with septicemia [23], and sedentary elderly subjects [24].

The effects of NMES training on muscle function in ESRD patients were investigated in small groups of maintenance hemodialysis (MHD) patients and in one group of chronic peritoneal dialysis patients [25–32]. The results of 2–3 months of NMES training showed increased strength of the leg extensors, which was associated with augmented quadriceps muscle area [29,30] and enhanced walk distance [29]. In two trials in chronic dialysis patients, NMES training improved maximal exercise capacity [31,32] and enhanced the anaerobic threshold (VO<sub>2</sub> AT), which is a measure of aerobic capacity with important correlations with physical conditioning and health [33]. Arterial stiffness, assessed by cardio-ankle vascular index and impaired endothelial function, was not influenced by NMES [29,31,32].

In comparative studies of NMES and cycling exercise during hemodialysis, the benefits on physical exercise capacity were similar with both treatments [20,30]. NMES treatment also improved pulmonary function in severely disabled patients with COPD [21]. In healthy

subjects an enhancement of whole-body glucose uptake was observed after treatment with NMES [34]. Routine blood chemistry measurements (creatinine, uric acid, hemoglobin, glucose, HDL- and LDL-cholesterol, triglycerides, and electrolytes) were not affected in several NMES studies. However, in one trial, a lowering of plasma urea was observed in both the NMES-treated and the active exercising groups [20].

Many parameters of quality of life, assessed by the short form of the Kidney Disease Quality of Life (KDQOL) questionnaire (SF-36), were improved after NMES treatment [26,32]. In particular, improvements in mental function and in some aspects of physical function were observed. The effects were similar to data published after active physical exercise training in patients with ESRD [7].

Altogether, these studies demonstrate striking effects of NMES on muscle strength of the lower limbs, functional capacity [6-minute walk test (6-MWT)], and measures of quality of life. The limitations of these studies are the small numbers of participants and the short intervention times. Therefore further investigations will be necessary with more participants and a longer follow-up to establish the potential benefits of NMES for ESRD.

### Effects of electrotherapy for pain in end-stage renal disease patients

Pain is a potential contributor to skeletal muscle wasting. Persistent pain may induce adverse physical, mental, and social consequences, including sleep disorders, anxiety, depression, and reduced daily physical activity [35,36], which favors the development of muscle wasting [37]. Peripheral polyneuropathy may also contribute to muscle wasting [38]. Approximately 50% of MHD patients suffer from chronic pain [39]. However, three-quarters of these patients are not effectively treated [40], in part, due to the polypharmacy taken by MHD patients and the frequent drug-related side effects of many analgesic agents that occur in ESRD [41,42].

Potential nonpharmacological strategies for chronic pain treatment in ESRD patients include physical exercise [43], psychiatric or spiritual counseling [44], meditation, relaxation techniques and hypnosis [45], as well as yoga-based programs [46]. The following forms of electrotherapy are treatments of interest that might have a role in pain management: transcutaneous nerve stimulation (TENS [47]), the so-called high-tone external muscle stimulation (HTEMs [48]), percutaneous nerve stimulation [49], and spinal cord stimulation [50].

FIGURE 53.1 Placement of TENS electrodes for the treatment of neuropathic pain. *TENS*, Transcutaneous nerve stimulation.

### Transcutaneous nerve stimulation

TENS is the most commonly used form of nonpharmacological pain treatment. It consists of a battery-powered portable electric unit with electrodes applied to the skin delivering electrical impulses to the underlying nerve fibers (Fig. 53.1). The frequency modes of TENS are high frequency (HF > 50 Hz), low frequency (LF < 10 Hz), and variable frequency [51]. In a placebo-controlled randomized study in diabetic patients, TENS treatment significantly improved the painful symptoms of distal symmetric polyneuropathy [47], pain associated with rheumatoid arthritis [52], and pain following various surgical procedures [53]. However, TENS treatment for lower back pain is not recommended [54]. Preliminary data indicate that TENS might also be effective for treating cancer-related pain [55]. A recent randomized pilot trial in individuals with dementia indicated that treatment with TENS appeared to raise the pain threshold and improve functional capacity [56]. Moreover, TENS therapy may be useful for patients with peripheral arterial disease and intermittent claudication [57].

### High-tone external muscle stimulation

Another option for pain treatment is referred to as HTEMs or high-frequency external muscle stimulation (Fig. 53.2). Here, continuously the initial frequency of 4096 Hz is increased up to 32,768 Hz within 3 seconds, remaining at this maximum for further 3 seconds and then downmodulated to 4096 Hz again. This allows for a more efficient stimulation of the muscles. In a short-term comparative investigation conducted for three consecutive days in patients with symptomatic diabetic peripheral polyneuropathy, HTEMs alleviated pain significantly more effectively than did TENS [48]. Daily treatment with HTEMs for 6 weeks in type 2 diabetic patients was followed by lowering of body

FIGURE 53.2 Placement of HEMS electrodes for the treatment of pain. HEMS, High-tone external muscle stimulation.

weight and significant improvement in diabetic control. Serum levels of some measures of inflammation also tended to decrease [58].

The effect of HEMS on symptomatic uremic and diabetic peripheral polyneuropathy was investigated in an uncontrolled multicenter study of 40 MHD patients [59]. Treatment was performed for 1 hour during hemodialysis three times per week. After 12 weeks of HEMS, there was a significant amelioration of tingling, burning, pain, numbness, and increased duration of sleep as compared to baseline values. These positive effects persisted for more than 1 year with exception of the improvement in sleep duration [60]. The blood chemical values, including C-reactive protein were not altered [59]. In a further uncontrolled investigation of health-related quality of life using the SF-36 scales in 25 MHD patients, 12 weeks of HEMS treatment resulted in a statistically significant improvement in the subscales of physical role functioning [61]. The beneficial effects of HEMS on painful uremic polyneuropathy were extended by Strembska et al. [62], who showed that the amelioration of pain was associated with a significant improvement in motor nerve conduction velocity. However, in none of the studies of TENS and HEMS, their effects on muscle dysfunction were investigated.

Since HEMS was shown to acutely increase renal blood flow in healthy subjects [63], its effect on the clinical course of patients with acute kidney injury (AKI stage 3) was studied in 34 patients with AKI who were randomized to either receive or not receive treatments with HEMS. The daily electrical HEMS therapy was associated with a significant shortening of the clinical course of AKI [64]. Moreover, HEMS therapy was associated with a significant reduction in the serum levels of nitric oxide (NO), asymmetric-dimethylarginine, and endothelin-1 in the AKI patients [65]. Interestingly, HEMS treatment in diabetic patients was also associated with an increase in vascular endothelial growth factor 2 in circulating hematopoietic stem cells and a decline in plasma catecholamines [66].

FIGURE 53.3 Forms of vibration trainings. Direction of vibration movement in synchronous and in side-alternating vibration. Source: Reproduced with permission from Rauch F, Sievanen H, Boonen S, Cardinale M, Degens H, Felsenberg D, et al.; International Society of Musculoskeletal and Neuronal Interactions. Reporting whole-body vibration intervention studies: recommendations of the International Society of Musculoskeletal and Neuronal Interactions. *J Musculoskelet Neuronal Interact* 2010;10(3):193–8, with permission.

In general, electrotherapy with NMES, TENS, and HEMS are well tolerated, but these treatments should be avoided in patients with cardiac pacemakers, implantable cardioverter-defibrillators, or other indwelling electrical stimulators.

### Whole-body vibration training

WBV exercise is another intervention modality to improve impaired muscle function [67]. WBV training is performed on motor-driven vibrating plates, which cause changes in the length of the muscle-tendon complex that evokes reflexive muscle contractions (Fig. 53.3) [68,69]. The electromyographic activity of the muscles is directly correlated with the frequency of the applied vibrations [70,71]. There are basically two different forms of WBV devices: in the synchronous operating platforms, both feet are moved up and down in parallel, while in the side alternating vibration one foot is moving up, while the other one is moving down inducing a sinusoidal vibration. The side-alternating plates are considered to act in a more physiological manner.

In the 1970s, Russian scientists used biomechanical stimulation of single muscles for cosmonauts to promote recovery after long flights. The first publication about WBV with a side-alternating device appeared in 1998 [72]. In a randomized controlled study, this training significantly improved the jumping performance. Later, WBV became increasingly popular among exercising adults and trained athletes who combine WBV with physical exercise training [73].

WBV has been shown to enhance muscle activity, force, power, balancing ability, and flexibility [74–76]. It enhances peripheral circulation [77,78] and reduces arterial stiffness, while blood pressure and heart rate did not change in most studies [79–81]. WBV was associated with improved glycemic control in type 2 diabetic patients [82]. During long-term bed rest, WBV training was also associated with the reduction of muscle and bone loss [83]. Moreover improvement in osteoporosis [84] and functional deficits of sedentary elderly subjects were shown [67,68,84]. Inconsistent results with WBV were reported in Parkinson's disease [85] and in multiple sclerosis [86]. Moderate improvement was achieved in stroke patients [87] and in patients with COPD [88]. Moreover, WBV may exert positive effects on chronic musculoskeletal pain [89] and the impaired functional performance of jump height and semitandem stance, which occurs during high-dose chemotherapy of patients with hematological malignancies [90]. The first studies with WBV in MHD patients were performed by Seefried et al. [91] where 14 participants used the side-alternating vibratory Galileo platform three times weekly before hemodialysis treatment for 3 months. The results showed a statistically significant improvement of the primary outcome, the Short Physical Performance Battery (SPPB), which is the sum of the scores of the Static Balance Test, the Gait Speed Test (GST), and the timed 5-Chair Rise Tests (CRTs). The training response was most pronounced in the subgroup in the lowest tertile for the SPPB score at baseline (Fig. 53.4). These findings are similar to results in MHD patients who were participating in an active exercise program [92].

The individual components of the SPPB showed only marginal changes for the GST, but substantial improvements for the static balance testing and the timed 5-CRTs. The secondary endpoints revealed

slight-to-moderate improvements in the Timed-Up and Go test, the distance attained in the 6-MWT, and in the jumping performance.

There was a mild, nonsignificant decrease in the systolic and diastolic blood pressure, which is in line with investigations of WBV in elderly subjects [68] and in overweight women [93,94]. Moreover, an increase in blood velocity and a decrease of arterial stiffness have been reported in people without kidney failure [80,81,95]. In the long run, it is possible that WBV may improve cardiovascular fitness [96].

Similar to active exercise [97], WBV training exerts antiinflammatory effects. In the study of Seefried et al. in MHD patients [91], a significant decline in white cell count was observed, while mean serum high-sensitive C-reactive protein decreased moderately but insignificantly. The WBV training was well tolerated. Patient-reported outcomes revealed a significant improvement of physical performance capability and mood.

The effects of WBV in 49 MHD patients were also investigated by Doyle et al. [98] in an uncontrolled trial using a vertical vibration platform. After an 8-week training period (three sessions for 3 minutes each per week), there was a significant improvement of the 60-second sit-to-stand test and an insignificant improvement of the Tinetti balance score. The quality of life assessment with SF-36 revealed significant improvement in two domains. Almost half of the patients dropped the study for reasons mainly unrelated to the training itself. According to the authors, treatment with WBV was well accepted by the patients; only one participant dropped out due to nausea after WBV.

For the prevention of falls, in particular in the elderly, the rapid force development at the beginning of muscle contraction is of fundamental importance. In advanced CKD patients the reaction time before rapid, forceful muscle contraction is considerably longer than

**FIGURE 53.4** Effect of WBV on the SPPB. Blue: significant increase of the whole group. Yellow: best results in the tertile with the most severe physical impairment. Red: results of the tertile with the least (only minor) physical impairment. SPPB, Short Physical Performance Battery; WBV, whole-body vibration. Source: Reproduced with permission of Seefried L, Genest F, Luksche N, Schneider M, Fazeli G, Brandl M, et al. Efficacy and safety of whole-body vibration in maintenance hemodialysis patients – a pilot study. *J Musculoskeletal Neuronal Interact* 2017; 17(4):268–74.

that of controls. In order to examine whether WBV might reduce the reaction time until rapid or explosive force is initiated, Fuzari et al. conducted a randomized, controlled trial in 14 hemodialysis patients [99] and demonstrated that WBV improved the reduced explosive force of knee extensor muscles. In another randomized controlled study in 16 MHD patients by Fuzari et al. [100], the effect of WBV on muscle power and mass was studied. After a 12-week training period (two WBV sessions per week) using a vertical vibration platform, a significant improvement of the maximum voluntary isometric contraction of the knee extensors was observed, while the thickness of the quadriceps muscle did not change. The walking capacity (6-MWT) and static balance increased insignificantly. Health-related quality of life (KDQOL) was not ameliorated.

In summary the few published studies of WBV training in ESRD patients suggest that this intervention may improve the impaired muscle strength of the lower legs, physical performance, and potentially some parameters of quality of life. These results are consistent with previous studies of WBV training in various other chronic diseases. Major limitations of the trials in MHD patients are the small number of participants, the short duration of the studies and, often, the lack of control groups. Therefore long-term randomized, prospective controlled trials with larger patient groups are needed to confirm the results of these studies.

4<sup>th</sup> Edition

# Nutritional Management of Renal Disease

Edited by  
Joel D. Kopple  
Shaul G. Massry  
Kamyar Kalantar-Zadeh  
Denis Fouque

***Nutritional Management of Renal Disease, 4th Edition*** offers in-depth reviews of the metabolic and nutritional disorders prevalent in patients with renal disease and serves as an in-depth reference source concerning nutrition and kidney disease. This classic translational reference provides correct diagnosis—and therefore correct treatment—of metabolic and nutritional disorders in acute kidney injury, chronic kidney disease, kidney failure, dialysis and kidney transplantation. Nephrologists, diabetologists, endocrinologists, dieticians, and nutritionists depend on a strong understanding of the molecular basis for the disease. This fourth edition includes thorough new case reports, offering expert advice on how to use the latest research and clinical findings in counseling patients about dietary and lifestyle options. Readers gain insight into which treatments, medications, and diets to use based on the history, progression, and genetic makeup of a patient.

## Key features

- Includes the latest comprehensive KDOQI clinical practice guidelines for the nutritional management of kidney disease from the National Kidney Foundation and the Academy of Nutrition and Dietetics, covering recommendations for each essential nutrient, as well as for some nonessential nutrients
- Presents a comprehensive, translational look at all aspects of metabolic and nutritional disorders in one reference
- Provides a common language for nephrologists, nutritionists, endocrinologists, and other interested physicians to assimilate information and discuss the underlying research and translation of best practices for the nutritional management and prevention of renal disease
- Saves clinicians and researchers time in quickly accessing the very latest details on nutritional practice as opposed to searching through thousands of journal articles.
